Despite the concerns mentioned above, carefully controlled clinical trials using iPSCs have just been initiated to repair age-related macula degeneration. In the fall of 2014, Dr. Masayo Takahashi, an ophthalmologist at the RIKEN Center for Developmental Biology initiated the first clinical trials in humans. She generated iPSCs and directed them to become retinal pigment epithelium cells. Thin sheets of these cells were transplanted into the damaged retina of a 70-year old patient. This historic trial, ultimately involving six patients, is ongoing and the end results are awaited with great anticipation. Extensive preliminary studies with primates suggested that tumor formation was low and immune rejection was not provoked.

Once the barriers described above are overcome, current discoveries are providing the proof of principle that cell-based therapies are feasible. Clearly, these studies are just the beginning of a tsunami of breakthroughs in this field and the near future will provide much information about the successes and failures of using pluripotent cells in regenerative medicine.

EDITORS-IN-CHIEF

Ralph A Bradshaw is Professor Emeritus in the Department of Physiology and Biophysics at the University of California, Irvine. Prior to that he was on the faculty of the Department of Biological Chemistry, Washington University School of Medicine in St. Louis, MO and was Professor and Chair of the Department of Biological Chemistry at University of California, Irvine. From 2006 to 2015, he was a member of the Mass Spectrometry Facility and Professor of Pharmaceutical Chemistry at the University of California, San Francisco. He holds degrees from Colby College and Duke University and was a post-doctoral fellow at Indiana University and the University of Washington. He has served as president of FASEB, was the founding president of the Protein Society and was the treasurer of the American Society for Biochemistry and Molecular Biology. His research has focused on protein chemistry and proteomics, with emphasis on the structure and function of growth factors and their receptors, particularly nerve growth factor and fibroblast growth factor, and the involvement of receptor tyrosine kinases in cell signaling. He has also studied the role of proteolytic processing and N-terminal modification in protein stability and turnover.

Philip D Stahl is E. Mallinckrodt Jr. Professor Emeritus at Washington University School of Medicine in St. Louis, MO. He was educated at West Virginia University with post-doctoral work at Vanderbilt University. He served as Head of the Department of Cell Biology and Physiology and Director of the Division of Biology and Biomedical Sciences at Washington University. He has been the recipient of many awards including a MERIT award from the NIH and the WICB Senior Recognition award given by the American Society for Cell Biology in recognition of his work supporting the advancement of women in science. Among StahlLab contributions are the discovery of the lysosomal enzyme clearance pathway now implemented in the treatment of lysosomal storage disease, discovery of the innate immune receptor, the mannose receptor, discovery of the exosome secretion pathway, and the role of Rab5 and Arf6 in endocytosis.

Currently his research focuses on endocytosis, signal transduction, and exosome biogenesis and secretion.

VOLUME EDITORS

Gerald W Hart is the Director and DeLamar Professor of Biological Chemistry at Johns Hopkins Medical School. He began his research on glycoconjugates about 40 years ago as a graduate student, and he has been active in the field of Glycobiology ever since. Among his research accomplishments, he determined the minimal sequence requirements for N-linked glycosylation while a postdoc in William Lennarz's lab, and he collaborated with Paul Englund's group at Johns Hopkins to elucidate the biosynthetic pathway for GPI-anchors. In the early 1980s, while probing cells with glycosyltransferases, Hart's laboratory discovered cytoplasmic and nuclear protein glycosylation by O-linked *N*-acetylglucosamine (O-GlcNAc) (e.g., *Journal of Biological Chemistry* 259: 3308; *Journal of Biological Chemistry* 261: 8049). Since that time, the Hart laboratory has published nearly 200 papers on O-GlcNAcylation, identifying and cloning the enzymes controlling cycling, characterizing O-GlcNAcylation and its interplay with phosphorylation on hundreds of proteins, and they have developed many of the tools and methods in use today to study this modification. In

1989, Hart founded the leading journal in the field, *Glycobiology*, serving as Editor-in-Chief until 2001. Hart received the first International Glycoconjugate Organization (IGO) Award in 1997, the Karl Meyer Award from the Society for Glycobiology in 2006, and served as the 2009–2011 president of the IGO. Hart is currently an Associate Editor for *The Journal of Biological Chemistry* and an Associate Editor for *Molecular and Cellular Proteomics*. To date, Hart has published about 263 papers, all in the area of glycosciences. H factor=84.

Bruno Goud studied biochemistry and immunology at the Ecole Normale Supérieure de Cachan and the University of Paris. He received his PhD in 1981 under the mentorship of Jean-Claude Antoine and Stratis Avrameas at Institut Pasteur and did postdoctoral work under the mentorship of Peter Novick at Yale University. In 1995, he established an independent research group in the Department of Cell Biology at the Institut Curie in Paris. The main focus of his studies is the regulation of intracellular transport and membrane trafficking in eukaryotic cells. In particular, his group is working on the functions of Rab GTPases, the mechanisms that sustain the global organization of intracellular compartments and the functions of myosins in membrane traffic. Since 2000, he has also developed original *in vitro* approaches to unravel physical parameters such as membrane tension or membrane curvature that underlie transport processes.

Bruno Goud is a recipient of an ERC (European Research Council) Advanced grant (2013). He is a member of the European Molecular Biology Organization (EMBO). He has been the Head of the Department of Cell Biology of Institut Curie since 2003.

Graça Raposo received her PhD in 1989 in Membrane Biology and Immunology at the University of Paris VII where she specialized in electron microscopy and membrane biology. From 1990 to 1995 she was a postdoctoral fellow at the Immunology Center in Marseille and then in the Department of Cell Biology, Utrecht University, The Netherlands. She is the deputy Director of the Department of Cell Biology at Institut Curie and Director of the Training unit. Her major research interests focus on the biogenesis and functions of exosomes and lysosome related organelles with implications in neurodegenerative disorders, lysosomal diseases, and cancer. Her group have started to unravel the cellular and molecular mechanisms regulating the biogenesis of melanosomes, the lysosome related organelles of epidermal melanocytes, studies that open a new avenue to modulate pigmentation in health and disease. In 2012 she was awarded the CNRS Silver Medal and in 2013 the Descartes Huygens Price from the Royal Dutch Academy of Sciences. She is a member of the European Molecular Biology Organization (EMBO).

Alan Ezekowitz, MBChB, DPhil, FAAP, is Co-Founder, President, and CEO of Abide Therapeutics, a company cofounded by Professors Dale Boger and Ben Cravatt from the Scripps Research Institute. He was previously Senior Vice President and Franchise Head, Bone, Respiratory, Immunology, Endocrine, Dermatology and Urology at Merck Research Laboratories. At Merck, he was responsible for the overall scientific direction of the drug discovery and development process. Prior to Merck, Dr. Ezekowitz was Chief of Pediatric Services at the Massachusetts General Hospital for Children and the Partners Healthcare System and the Charles Wilder Professor of Pediatrics at the Harvard Medical School. He chaired the committee that led to the establishment of the Academy at the Harvard Medical School where he served as a Scholar and Founding member. He served on the Board of Directors of the Partners Healthcare System and Massachusetts General Physicians Organization. In 2008 he was honored with the establishment R. Alan Ezekowitz Professorship in Pediatrics at the Harvard Medical School.

He is a member of the American Society of Clinical Investigation, the Association of American Physicians, the American Pediatric Society, and a Fellow of AAAS. He served on NIH Subcommittees on Biodefense and Vaccine Adjuvants; NAS panels on antibiotic resistance and academic pharmaceutical partnerships; and the ARISE 2 task force of American Academy of Arts & Science that is evaluating the impact of federal and industrial funding of science, engineering, and medicine on American universities.

Dr. Ezekowitz received his MBChB and DPhil from University of Cape Town and Oxford University, respectively. At Children's Hospital in Boston, he was a postdoctoral fellow in the Division of Hematology and Oncology with clinical training in pediatrics. He was on the staff of the Children's Hospital of Boston prior to moving to the Massachusetts General Hospital.

He is a pioneer in the field of innate immunity and has over 150 publications. In particular his group played a major role in defining the structure function of the mannose binding lectin and the macrophage mannose receptor.

Douglas A. Lauffenburger is Ford Professor of Bioengineering, and cofounder and Head of the Department of Biological Engineering at MIT, with affiliate appointment in the Department of Biology; he was a founding codirector of the MIT Computational and Systems Biology Initiative in 2002. His major research interests are in cell engineering, with central focus on cell-cell communication and intracellular signal transduction, emphasizing predictive computational models derived from quantitative experiment. Lauffenburger has coauthored a monograph entitled *Receptors: Models for Binding, Trafficking & Signaling* (Oxford University Press, 1993), has coedited the book entitled *Systems Biomedicine: Concepts and Perspectives* (Elsevier, 2010), and has supervised more than 100 doctoral and post-doctoral students. He is a member of the National Academy of Engineering and the American Academy of Arts and Sciences, and has served as President of the Biomedical Engineering Society, Chair of the AIMBE College of Fellows, and on the NIH NIGMS Advisory Council, and coauthored the NRC report on *A New Biology for the 21st Century*.

SECTION EDITORS

Kenneth E Neet received his PhD in Biochemistry in 1965 (with Dr. Frank W. Putnam) from the University of Florida. He was a postdoctoral fellow at the University of California, Berkeley (with Dr. Daniel E. Koshland, Jr.), and joined the faculty of Case Western Reserve University (CWRU) in 1967 as an Assistant Professor of Biochemistry.

Dr. Neet received a Faculty Research Award of the American Cancer Society from 1968 to 1973 and was on sabbatical leave at the National Institute for Medical Research, Mill Hill, England (with Dr. N. Michael Green) 1973–1974. From 1978 to 1990, he was Professor of Biochemistry at CWRU. During 1980–1981, he took a sabbatical year as a Josiah Macy Faculty Scholar in the Department of Neurobiology, Stanford University (with Dr. Eric M. Shooter).

Dr. Neet moved to Rosalind Franklin University of Medicine and Science/The Chicago Medical School in 1990 and was Professor and Chair of Biochemistry & Molecular Biology until 2005. Dr. Neet became Associate Dean for Research of the Chicago Medical School, RFUMS in 2004.

Dr. Neet has served on the Editorial Boards of the *Journal of Biological Chemistry*, *Protein Science*, and *Molecular & Cellular Proteomics* and as a member of study sections for the National Institutes of Health and the National Science Foundation. He was an Associate Editor of the *Journal of Biological Chemistry* (1996–2013).

Dr. Neet's research interests have been in the general areas of protein–protein interactions, allosteric interactions, protein conformational changes, and cell signaling. In his earlier years he studied theoretical and experimental aspects of slow transitions in enzymes, particularly the cooperativity of the monomeric enzyme glucokinase. Later, he studied ligand–receptor interactions of nerve growth factor, establishing a mutational system to study the interactions with its receptors (TrkA and p75), and ultimately the complex signaling emanating from these receptors within neuronal systems.

Sarah A Woodson is a biophysical chemist interested in how RNA molecules fold into specific three-dimensional structures and how they interact with proteins to turn genes on and off in the cell. She was born in Michigan, USA, and attended Kalamazoo College before receiving her PhD in Biophysical Chemistry from Yale University in 1987. After postdoctoral research in the laboratory of Tom Cech at the University of Colorado Boulder from 1987 to 1990, she joined the faculty of the University of Maryland in 1990 and the faculty of Johns Hopkins University in 1999, where she is currently the T.C. Jenkins Professor of Biophysics. Together with Mark Chance and Michael Brenowitz, she pioneered methods for visualizing how RNA molecules change shape in real time. She served on the board of the RNA Society and was elected an AAAS Fellow in 2011 and a Pew Scholar in the Biomedical Sciences in 1993. She is currently a reviewing editor of *Biopolymers* and *Journal of Molecular Biology* and serves on the editorial boards of *Nucleic Acids Research* and *RNA*.

Judith S Bond, Evan Pugh Emeritus Professor of Biochemistry and Molecular Biology at the Pennsylvania State University College of Medicine, was President of the Federation of American Societies for Experimental Biology (2012–13) and an Associate Editor of the *Journal of Biological Chemistry* (1999–2013). She received her BS degree from Bennington College in Vermont, her PhD from Rutgers University, and did postdoctoral research at Vanderbilt University. She rose through the academic ranks at the Medical College of Virginia, Virginia Commonwealth University, became Professor and Head of Biochemistry and Nutrition at Virginia Polytechnic Institute and State University, and served at Penn State University College of Medicine as Professor and Chair of Biochemistry and Molecular Biology from 1992 to 2012. At Penn State, she also served as assistant dean for graduate studies, codirector of the All-University Interdisciplinary Biological Sciences Program and founding director of the Medical Scientist Training Program. She recently directed NIH-funded summer research programs for high school students and teachers and for undergraduate students (particularly underrepresented minority groups). Her work on metalloproteases has been funded continuously by the NIH for over 35 years. She has

trained 5 Master's, 21 PhD students, and 19 postdoctoral trainees. Her professional service included member and chair National Institutes of Health Study Sections, member of the National Institute of Diabetes, Digestive and Kidney Diseases Advisory Council, member of the American Association of Medical Colleges – Howard Hughes Medical Institute Committee on the Scientific Foundations for Future Physicians, and President of the American Society for Biochemistry and Molecular Biology.

Elliot L. Elson received his AB at Harvard, his PhD at Stanford under the mentorship of R.L. Baldwin and did postdoctoral work at University of California, San Diego, under Bruno Zimm. His first independent faculty position was in the Department of Chemistry, Cornell University, where he stayed for 11 years. He then moved to the Department of Biological Chemistry (now the Department of Biochemistry and Molecular Biophysics) at Washington University in St. Louis, School of Medicine. He has pursued research in several biophysical areas. One of these is the development of Fluorescence Correlation Spectroscopy and Fluorescence Photobleaching Recovery and their application to studies of diffusion in cell membranes and of phase separation in model membrane bilayers as well as of other cellular and noncellular phenomena. He has also worked in the areas of cell mechanics, cell motility, and the mechanical properties of engineered tissues. His laboratory has developed approaches for measuring mechanical properties of cells in monolayer culture and for determining the contributions of cells and extracellular matrix to the mechanics of engineered heart and connective tissue constructs.

Tamotsu Yoshimori received his PhD degree in 1989 at Osaka University. After working at several places including European Molecular Biology Laboratory (Prof. Kai Simons' lab) and National Institute of Basic Biology (Prof. Yoshinori Ohsumi's lab), he is now a distinguished professor of Osaka University (Graduate School of Medicine and of Frontier Biosciences). His research interests are focused on intracellular membrane trafficking, and especially for the last 18 years, on autophagy. He identified LC3 as an autophagosome-binding protein, which has been widely used as the gold standard in autophagy assays. The paper has been cited over 3000 times. He also provided new insights into membrane biogenesis in autophagy and the role of autophagy in pathogen defense and suppression of various diseases. He authored or coauthored over 220 journal articles and book chapters. He is an editor of *Journal of Cell Science*, and on the editorial board of *Journal of Cell Biology*, *Molecular Biology of the Cell*, and so on. He is a member of the Faculty of 1000 and a vice president of Japan Society for Cell Biology. He was awarded Osaka University Presidential Award for 2012 and 2013, Prize for Science and Technology by the Minister of Education, Culture, Sports, Science and Technology in 2013, Kakiuchi Saburo Memorial Prize by the Japanese Biochemical Society in 2014, and selected as Highly Cited Researchers 2014 by Thomson Reuters.

Paul A. Gleeson is currently Head of the Department of Biochemistry and Molecular Biology at the University of Melbourne, located at Bio21 Institute. His research interests include the molecular mechanisms of intracellular membrane transport and the molecular basis of organ-specific autoimmune diseases. Paul Gleeson obtained his PhD in 1980 from the University of Melbourne and did postdoctoral research in the biosynthesis and function of glycoproteins at the Hospital for Sick Children, Toronto, National Institute for Medical research, Mill Hill London and Department of Biochemistry, La Trobe University, Melbourne. He established an independent laboratory at Monash University in 1986 where he defined the targeting signals of Golgi glycosyltransferases, identified golgins of the *trans*-Golgi network and along with his colleagues developed mouse models of autoimmune gastritis. In 2001 he moved to Department of Biochemistry and Molecular Biology at the University of Melbourne and has been Head of the Department since 2006. He has a number of international research collaborations and has been a visiting scientist at the EMBL, Heidelberg, and the Institut Curie, Paris.

Anna Akhmanova studied biochemistry and molecular biology at the Moscow State University. She received her PhD in 1997 at the University of Nijmegen, the Netherlands. She worked as a postdoc at the Department of Microbiology and Evolutionary Biology at the University of Nijmegen and at the Department of Cell Biology at the Erasmus Medical Center in Rotterdam, the Netherlands. In 2001, she started her own research group at the Erasmus Medical Center. Since 2011, Anna Akhmanova is professor of Cell Biology at Utrecht University, the Netherlands.

Akhmanova studies cytoskeletal organization and trafficking processes, which contribute to cell polarization, differentiation, vertebrate development, and human disease. The main focus of her studies is the microtubule cytoskeleton. Her group has described key interactions between proteins associated with microtubule ends and determined their role in the regulation of microtubule organization and dynamics. She has also characterized mechanisms of bidirectional microtubule-based motility of membrane organelles such as cell nuclei and exocytotic vesicles. Her research relies on combining high-resolution live cell imaging and quantitative analysis of cytoskeletal remodeling, measurement of protein dy-

namics using advanced microscopic assays, *in vitro* reconstitution of dynamic cytoskeleton-based processes and different methods of identification of protein-protein interactions.

Anna Akhmanova is a recipient of the ALW Vernieuwingsimpuls VIDI (2001) and VICI awards (2007) (Netherlands Organization for Scientific Research), and an ERC Synergy grant (2013). She is the Chair of the board of the Netherlands Microscopy Society and a member of the European Molecular Biology Organization (EMBO).

Yosef (Yossi) Yarden is a Professor in the Department of Biological Regulation at Weizmann Institute of Science (Rehovot, Israel). Dr. Yarden obtained his PhD from Weizmann Institute (under the mentoring of Dr. Joseph Schlessinger) and later trained at both Genentech Inc., with Dr. Axel Ullrich, and at the Whitehead Institute (MIT), with Dr. Robert A. Weinberg. His group studies the roles played by growth factors and their receptors in cancer progression. They also explore strategies able to intercept growth factor signals in tumors.

Jason D Weber is an Associate Professor in the Departments of Internal Medicine and Cell Biology and Physiology at Washington University and is the Coleader of the Breast Cancer Research Program in the Siteman Comprehensive Cancer Center. Dr. Weber obtained his PhD from Saint Louis University and received postdoctoral training under the mentoring of Dr. Charles J. Sherr at St. Jude Children's Research Hospital in Memphis, TN. His group studies the molecular interplay between oncogenes and tumor suppressors, particularly focused on their role in regulating cellular growth processes.

Michael Dustin received his PhD in 1990 in Cell and Developmental Biology from Harvard University, where he worked in the laboratory of Timothy A. Springer, PhD. During his graduate work he was involved in the identification and cloning of ICAM-1 and ICAM-2, key ligands for the integrin LFA-1. He further demonstrated that LFA-1 dependent adhesion was stimulated by T cell receptor signaling. He did his postdoctoral training with Stuart Kornfeld at Washington University School of Medicine in St. Louis, focusing on mechanisms of lysosome biogenesis. He started his independent lab also at Washington University School of Medicine, and used supported lipid bilayers to define the first protein to modulate organization of the immunological synapse- CD2 associated protein- and the dynamics of immunological synapse formation. He moved to NYU School of Medicine in 2001 where he applied *in vivo* microscopy to tolerance induction and immune responses in effector sites including the liver, brain, and spleen. Continued work with the immunological synapse model resulted in discovery of signaling microclusters, the molecular basis of immunological synapse stability, and the direct budding of extracellular microvesicle enriched in T cell receptors in the immunological synapse. Professor Dustin recently took a position at the

University of Oxford with support of a Wellcome Trust Principal Research Fellowship. The focus of his new post is the translation of the immunological synapse. He received a Presidential Early Career Award in Science and Engineering and the DART-NYU Biotechnology Achievement Award.

David A. Sassoon directs a research team at Paris Sorbonne. He received his PhD from Columbia University (NYC, USA) in 1986 in the biological sciences and was a professor at Boston University Medical School and Mt. Sinai Medical School before relocating to Paris in 2006. His long-standing interests are in developmental and stem cell biology in a number of tissues including skeletal muscle, skin, CNS, and heart. Dr. Sassoon recently concluded the coordination of a EC-funded 15 partner international consortium (Endostem) designed to identify novel therapeutics for mobilizing endogenous stem/progenitor cells (<http://www.endostem.eu/>) and is a recent recipient as coordinator of a multipartner Transatlantic Network of Excellence grant from the Fondation Leducq focused on cardiac stem cell biology (<http://www.fondationleducq.org/nivel2.aspx?idsec=1360>).

A major focus of his research is on adult progenitor/stem cell biology and how these cells respond to stress. His team has identified a parentally imprinted gene, PW1/Peg3, which is involved in both p53 and inflammatory responses. PW1 is expressed in adult stem cells in all tissues identified to date. Loss of PW1 function in stem cells results in a loss of stem cell competence including a reduced capacity to undergo self-renewal and respond to hypoxic stress. We are currently evaluating a role for PW1 in postnatal and adult heart with a particular focus on its role in vessel precursors using both myocardial infarction and stress-induced myocardial hypertrophy.

Jason M. Haugh is a Professor of Chemical and Biomolecular Engineering at North Carolina State University in Raleigh, NC, USA, where he has been on the faculty since 2000. His laboratory has been among those to pioneer the synthesis of quantitative experiments and modeling to study signal transduction in mammalian cells. Since the lab's inception, their approach has combined biochemical measurements, live-cell fluorescence microscopy, and computational modeling to elucidate signaling mechanisms by analyzing their kinetics and spatial organization in cells. The systems studied by the Haugh Laboratory include: regulation of the phosphoinositide 3-kinase, Ras/extracellular signal-regulated kinase, and phospholipase C pathways mediated by receptor tyrosine kinases, and cross talk between these pathways; dynamic organization of multimolecular complexes at cell membranes; signaling mediated by cytokine and chemokine receptors in immune cells; and integration of adhesion, signaling, and cytoskeletal dynamics that direct cell migration.

After graduating with an MA in Mathematics from the University of Cambridge, Helen Mary Byrne received her Master of Science and DPhil from the University of Oxford. She worked as a postdoctoral researcher at the Universities of Oxford and Bath, before taking up a lectureship at the UMIST in Manchester. She moved to the University of Nottingham in 1998 and was awarded a prestigious Advanced Research Fellowship from the United Kingdom's Engineering and Physical Sciences Research Council (2000–2006). She was promoted to Reader in 2002 and Professor in 2003. While in Nottingham, she established and then led the Centre for Mathematical Medicine and Biology until she returned to Oxford in 2011 where she is now based in the Mathematical Institute at the University of Oxford. She has over 20 years' experience of developing, analyzing, and simulating continuum and multiscale models of biomedical systems, and a particular interest in studying the growth and response to treatment of solid tumors.

Rune Linding completed his PhD at the European Molecular Biology Laboratory (EMBL) in Heidelberg, Germany, followed by postdoctoral training at EMBL. He then jointly trained with professors Tony Pawson and Mike Yaffe at the Lunenfeld at Mount Sinai Hospital in Toronto, Canada, and the Massachusetts Institute of Technology (MIT) in Cambridge, US, respectively. Dr. Linding then established his own laboratory of Cellular and Molecular Logic at the Institute of Cancer Research (ICR) in London, UK, before returning to Denmark to take a position as professor of cellular signal integration at the Technical University of Denmark. In 2014, Dr. Linding moved his laboratory to the Biotech Research and Innovation Centre (BRIC) at University of Copenhagen where he is currently professor of cellular signaling. His research group focuses on big data network biology, exploring biological systems by developing and deploying algorithms aimed to predict cell behavior, in particular looking at cellular signal processing and decision making. A strategic focus is to continue to develop computational tools (such as KinomeExplorer, NetworKIN, and NetPhorest) and to deploy these on genome-scale quantitative data obtained by, for example, mass spectrometry, genomic, and phenotypic screens to understand the principles of how spatio and temporal assembly of mammalian signaling networks transmit and process information at a systems level in order to alter cell behavior. His overarching aim is to advance network

medicine by identifying and targeting signaling networks associated with complex diseases. To this end Dr. Linding is currently leading high-level, strategic, multidisciplinary studies of signaling network dynamics driving cancer metastasis in collaboration with other labs at Harvard, Yale, The Jackson Laboratory, Memorial Sloan Kettering Cancer Center, MIT, and BRIC.

PREFACE

Cell biology is the study of cells, the integral unit that is the basis of all living tissues. In its earliest phases, this area of investigation was largely defined by microscopic-based observations of structure and organization that were, by their nature, largely descriptive. This also served to delineate cell biology from its nearest neighbor, biochemistry, which, dating from its post WWII renaissance, was driven in large part by reductionist approaches, where tissues, cells, and organelles were broken down in order to isolate and then characterize individual components. The melding force that bridged these two areas was molecular biology that allowed the cell biologist to transform pictures into functions and allowed the biochemist to reassemble their components into ensembles and subcellular entities. Not surprisingly the boundary between these two key biological sciences has become blurred beyond recognition. Today a considerable part of what passes as cell biology is by any other name biochemistry (or molecular biology – the distinction between these two areas being equally indistinct) and vice versa. Indeed, one of the first challenges we faced in organizing this Encyclopedia was how much molecular detail to include. It was our conclusion that for the sake of completeness, and to appropriately introduce the volumes Organizational Cell Biology and Functional Cell Biology, we needed a description of the molecular components of the cell, particularly with respect to the synthesis and degradation of proteins and nucleic acids, along with outlines of important chemical principles and key methodology. We were guided to some degree in these decisions by input from undergraduate and graduate teachers and the contents of their introductory courses that they shared with us and by discussions with our volume and section editors. The result was the first volume which we recognize is very 'biochemical,' but certainly lacking the more detailed coverage of the *Encyclopedia of Biological Chemistry* (Lennarz and Lane, 2004) or the many excellent biochemical texts that dot the educational landscape. Readers who find 'gaps' or incomplete treatments in this section will likely be able to find the additional detail they seek from these sources.

The second major decision that we had to confront was whether we would attempt to cover the full range of living organisms or whether we would place some limits on the scope of the material we included. In the final result, it was decided to place the emphasis on higher eukaryotes with only very prescribed treatments of lower eukaryotes and prokaryotes. Volumes 2 and 3 thus deal with material that has perhaps been more traditionally thought of as cell biology. Again we were guided in our decisions about what to include by teaching considerations, brainstorming sessions with our editors, and a perceived need to separate cellular organization from cellular function. However, as even a quick perusal will reveal, this is not a sharp delineation either. Volume 2 begins with a methodological treatment of imaging, which is basically divided between light and electron microscopic applications, and is followed by sections on organelles, interorganellar communication, and the cytoskeleton (including motors). The

last part of volume 2 is devoted to intracellular infection and covers a variety of external agents and pathogens that impact cell function as well as human pathology. Volume 3, in contrast, largely deals with major cell functions: signaling, cell-cycle control, and apoptosis. The last two parts are devoted to cells of the immune system and their responses and stem cells – two highly specialized niches characterized by unique cellular involvement.

The last part of the Encyclopedia deals with systems biology. This is really the newest area of cell biology and considers cellular involvement as part of a phenotypic response. As such, it strives to integrate all of the levels of the first three volumes in a consistent manner to produce a seamless description of cellular function. This is clearly a newly evolving area and the most rapidly changing part of cell biology; indeed it is where we expect to see the greatest change in the next few years.

Assembling a treatment of a topic as large as cell biology had multiple challenges. Coverage was a significant problem: on the one hand it was almost impossible to avoid some redundancy in places while, on the other, there were inevitable gaps. Some of these arose from late cancellations; others from oversights on our part. We can only promise to fill these in future editions. We also note that as can be expected for a large multiauthor compilation the individual articles do differ in detail and treatment. We felt it was more important to allow our experts substantial latitude in deciding how to present their topics than to apply rigid guidelines. We did try to limit the number of references (to make it easier for people not familiar with a topic to make the transition to more extensive articles) but there is admittedly some considerable variation in the bibliographic material as well.

When we were well into the project, we were approached by Graham Nisbet (Elsevier) about including the Encyclopedia in a larger collection entitled the Reference Module in Biomedical Sciences. The Reference Module plan was grouped in single integrated work information from several other compendia and it was our view that this would greatly leverage the value of our efforts (and those of our contributors). While we were the 'new kid on the block' in that we were still compiling the Encyclopedia and the other collections to be included were already extant, we felt that it was too good an opportunity to pass up. The Reference Module has since been launched and although it does not yet contain the complete content from the Encyclopedia, this will be achieved in the not too distant future. We consider that this will be a particularly valuable resource for researchers that are just entering (or changing into) this field.

No work of this size could be completed without the help and advice of many people. In this regard we would like to thank a number of people who were instrumental in bringing this project to fruition. First and foremost we would like to recognize our volume editors: Jerry Hart, Graça Raposo, Bruno Goud, Alan Ezekowitz, and Doug Lauffenburger; and our section editors: Ken Neet, Sarah Woodson, Judy Bond,

Elliot Elson, Tamotsu Yoshimori, Paul Gleeson, Anna Akhmanova, Yosef Yarden, Jason Weber, Michael Dustin, David Sassoon, Jason Haugh, Helen Byrne, and Rune Linding; and thank them for their invaluable input, enthusiasm, and hard work. They are truly a global group and have been a great team to work with. We also wish to thank the staff at Elsevier including Janice Audet, Peter Labella, Nicky Carter, Karen Maloney, Erin Hill-Parks, Rashmi Phadnis, Blerina Osmanaj, and Ginny Mills for their many efforts, perseverance (particularly with our idiosyncrasies), and skillful management of every aspect of this project.

In the course of planning this work, we gathered information from a number of sources. At the outset the publishers polled some 167 faculty from both undergraduate and graduate schools to ascertain their perceived interest in such a project, which also garnered considerable input about potential topics. The response was highly favorable. We also talked with many colleagues about experiences at their institutions and would like to particularly thank Catherine Bevier (Colby College), Robert Simoni (Stanford University), Larry Marsh (UC Irvine), and John Cooper (Washington University) for providing syllabi of germane courses taught in their institutions. Special thanks also go to Ruedi Abersold (ETH, Zurich) and Sergio Grinstein (University of Toronto) for their expertise that they readily shared with us, which was invaluable in planning certain sections.

Finally we would like to recognize all of our authors. We have been extraordinarily fortunate in attracting individuals from all around the globe to take time from their busy schedules to prepare this splendid set of contributions. Without these efforts there would be no Encyclopedia. Under ordinary circumstances it would be appropriate to dedicate the work to them and all the colleagues whose works they wrote about. However, during the preparation of this work, we sadly lost one of the most important contributors to cell biology, Tony Pawson. Tony was a true pioneer in elucidating basic mechanisms of how cells transmit information intracellularly, a fundamental knowledge that permeates all of cell biology. In an effort that was initiated by one of the section editors, Rune Linding, it was decided to dedicate the entire work to his memory as recognition of his contributions and a lasting tribute to a man who left us too soon.

We hope that the Encyclopedia will be of value to students and researchers alike and will become a useful tool in the training of future generations of scientists.

Ralph A Bradshaw and Philip D Stahl

All living organisms can be divided into three principal categories: archaeobacteria, eubacteria, and eukaryotes; although they differ in structure and organization, they are all composed of cells as the fundamental life unit. At the molecular level, there is also a great deal of similarity in the basic materials that make up these entities because they use the same kinds of molecules to store and reproduce information, to run the cellular metabolism and machinery and to provide the structural framework. Thus nucleic acids, proteins, lipid membranes, and carbohydrates – alone and in various combinations – are universally present, albeit in distinguishable forms, along with innumerable metabolites and ions. There are components that are apparently essential for life and are found in one form or another in all species and there are many unique moieties and associated activities that are highly specialized and are found in relatively few organisms. Indeed, the similarities have underpinned the development of our understanding of cellular function at a rudimentary level and the differences, basically engendered by evolution, have illustrated and delineated the complexity that speciation has introduced. Perhaps the largest of these differences is that which separates single cell organisms from multicellular organisms. The latter are exclusively eukaryotes while the former are composed of both eukaryotes and prokaryotes. The cellular organization and architecture that distinguishes these two major life forms is striking; although cell biology correctly embraces both, traditionally prokaryotic organisms have been the province of the microbiologists and the majority of cell biology research has been devoted to the eukaryotic world. In practical terms this translates for the most part into the study of human cells and those of easily maintained laboratory animals and selected paradigms, for example, fruit flies, worms, and zebra fish.

Human and animal cell biology is not a tightly proscribed science with well-defined borders. Basically it serves at the interface between biochemistry, molecular biology, and genetics, on the one hand, and anatomy and physiology, on the other. The continuum of these disciplines forms the core of the biomedical sciences, which also include the related but separate fields of pharmacology, microbiology, immunology, and pathology that provide the connections to disease and health. Cell biology has strong connections to all of these. There are also specialized areas, for example, neuroscience, that are of such importance that they warrant their own category and the cell biology associated with them is also highly specialized. Thus, cell biology is as complex as the enormous variety of cells that exist and achieving an accurate description of all of them in terms of their components and functions has long been a major part of the research in this field.

Imaging and Organelle Organization

Among the developments that propelled cell biology into the modern era are the introduction of the ultracentrifuge and

the rapid advances in microscopy both electron and light microscopy – the former allowing investigators to fractionate and characterize the components of the cell and the latter to literally see them – either *in situ* or in isolated form. This progress is illustrated by a series of Nobel Prizes starting in the early 1970s that chronicle the grand confluence of classical biochemistry and general physiology that created modern cell biology (Claude *et al.*, 1974) or the discovery and characterization of intracellular organelles – lysosomes and endoplasmic reticulum (ER) among others (Mitchell, 1978), for the chemiosmotic hypothesis (Brown and Goldstein, 1985), for endocytosis (Ciechanover *et al.*, 2004), for ubiquitination and protein degradation, and just recently (Rothman *et al.*, 2013), for vesicle trafficking, and (Betzig *et al.*, 2014) for advances in light microscopy. The early cell biologists insisted on quantitative application of these new techniques and laid the groundwork for modern cell biology. As with biochemistry, reductionism has been the keystone for the amazing success over these past several decades. Each organelle has its own research history – the nucleus, mitochondria, peroxisomes, the proteasome, the ER, and cytoskeleton. The Golgi apparatus/secretory pathway and the endosome–lysosome network have all been examined in detail both in isolation and in their relationships with each other. A new member, the exosome (aka extracellular vesicle) has emerged more recently and stimulated the imagination of aspiring young investigators (Harding *et al.*, 2013). The rise of genomics, the development of spectacular imaging modalities, and evolving biochemical techniques (proteomics) have led to the discovery of molecular motors, the identification of macromolecular complexes such as the exocyst, ESCRT, GARP, SNAREs among others that choreograph complex intracellular pathways, including cell motility and cytokinesis, have brought cell biology into this new era where the whole is now seen as larger than the individual components. This creates the segue from Parts 1 and 2 of the *Encyclopedia (Molecular Cell Biology and Organizational Cell Biology)* to Part 3 (*Functional Cell Biology*) where signaling modalities will be seen as an integrative force for regulation and control.

Signaling

While all organisms can sense their environment and respond to cues from it, multicellular organisms must in addition coordinate their responses, which require intercellular communication at a sophisticated level (Bradshaw and Dennis, 2009). The higher the development, the more complex these communication systems become. Thus the cell biologist must focus not only on how molecular function is translated into cell organization and how these functions are coordinated from organelle to organelle but also on the external interactions and signals that control the larger functional responses of organs and ultimately organisms.

Intercellular communication is afforded by stimuli that can be transmitted across the cell membrane, either directly or via membrane bound molecules that in turn pass signals to the intracellular compartment. The origins of these stimuli may be quite diverse. Among other things, they can include cell–cell contacts, soluble factors/messengers, or foreign agents. Lipophilic molecules can cross the membrane by diffusion or by facilitated transport to recognize and bind to intracellular entities but most substances bind to membrane bound proteins and induce their signal by ‘activating’ them instead. These so-called receptors are capable of producing a variety of responses that invariably involve the generation of posttranslational modifications of preexisting proteins. Protein phosphorylation, which in eukaryotes mostly occurs on tyrosine, serine, and threonine residues, is highly prevalent and appears to be directly or indirectly involved in almost all transmembrane signaling (Gnad *et al.*, 2011). However, it is by no means the only vehicle for transmitting information as acetylation, methylation, monoglycosylation, and ubiquitination, to name a few, are both important and widespread. There are over three hundred different covalent modifications (Khoury *et al.*, 2011) that are introduced into proteins (and many more that have not yet been chemically defined) of both a transient and stable nature and most are likely to be involved to some extent in signal transduction processes. In addition, limited proteolysis can also be an important part of a pathway and this activity is a major player in cellular responses (Turk *et al.*, 2012).

The induction of an intracellular signal is basically perpetrated by the formation of new interactions between the modified proteins and other entities, which can range from small molecules to macromolecular protein complexes. One of the most important advances in understanding how cells process information induced from external stimuli was the appreciation that the newly formed sites produced by the protein modifications were recognized by other proteins with modules specifically designed for this purpose (Pawson, 1995). Thus, for example, phosphotyrosine residues could be recognized by other proteins containing a domain, termed SH2 for its relatedness to a similar domain found in the Src protein kinase, which could then be further modified allowing for additional interactions to occur. By these ‘docking’ events, signaling complexes could be assembled, often in multiple steps, that ultimately lead to the activation of key effectors. The end point of many of the pathways is the activation of transcription factors that lead to the modulation of gene expression of that cell by ultimately changing its protein expression profile (Bradshaw and Dennis, 2009). However, many molecules are usually modified and activated ‘along the way’ and these ‘new’ activities also add to the overall response to the original stimuli. Short term responses indeed require that the protein effectors necessary for it are already present; long term responses per force require new protein synthesis.

Signal transduction is thus dependent on two phenomena: posttranslational modifications, particularly of the readily reversible type, and protein–protein interactions. The extent to which these two activities take place, even in resting, unstimulated cells was greatly underestimated before the advent of proteomics and the introduction of mass spectrometric methodology into cell biological research (Bradshaw and

Burlingame, 2005). These high-throughput unbiased analyses of very complex mixtures, basically derived directly from cell lysates, revealed that essentially every protein had multiple interacting partners and that posttranslational modifications affected a very significant proportion of the proteins present. These were profound differences from what had been the prevailing wisdom and amounted to a paradigm shift in thinking about cellular organization and structure. As noted above, these same tools have gone on to cast new light on organelle organization in terms of resident proteins and have helped to disclose the structure of important cellular machines, such as the proteasome (Voges *et al.*, 1999), the nuclear pore (Routa *et al.*, 2000), and transcription complexes (Kornberg, 2007). They have also begun to elucidate the complexity of epigenetic regulation of gene transcription at the histone level (Cosgrove, 2012), which will also be essential in completing our understanding of signaling processes.

Concluding Remarks

Two of the most fundamental aspects of cells are their ability to reproduce themselves and, in higher organisms, to undergo changes that lead to new cell types and functions. These developmental processes leading to differentiation are what allow a single fertilized egg to form a complex adult organism and require the synthesis of all aspects of cell biology to understand. Knowing how cells go from one state to another in a timed and regulated fashion forms the core of developmental biology, which can be viewed as a sub discipline of cell biology. Also of major importance is the maintenance of viability and the associated turnover processes. The control of cell death is not only an essential part of development it is also key to managing situations that have gone awry and underlies many serious disease conditions.

It is clear that science is still a long way from understanding how even simple cells work. There is a long list of functions and structures that remain to be elucidated and integrating the various experimental approaches and the data they produce still lags far behind. This is the ‘Era of Big Data’ and vast amounts of new information that impact on our understanding of cells and their processes are collected every day. Genomic information is a good example – despite the rapidity that this sort of information can now be obtained, it still remains to be effectively mined in terms of what it can tell us about basic principles of how cells work. There has been an understandable pressure to apply this information to managing disease (Collins and Varmus, 2015), particularly those that are life threatening, but there certainly is information that is yet to be formulated that would apply to fundamental problems as well. The same can be said for transcriptomics, proteomics, and metabolomics. In addition to these powerful new technologies, singular advances in analyzing single cells promises to augment these molecular approaches significantly (Di Palma and Bodenmiller, 2015).

One aspect of cell biology that is looking to address the challenges of integrating these relatively newly minted studies is systems biology (Part 4). It is far too early to assess the value of these efforts in coordinating this flood of information but it certainly looks promising. It will be an elusive goal for some

time to come but also a stimulus for new generations of cell biologists that will be forthcoming.

Understanding cell behavior has always been realized to be a complex problem requiring integration of operation of multiple molecular components involved in myriad functional and regulatory processes, intracellular and extracellular. Over the past decade or so, however, advances in experimental methodologies have facilitated direct address of this complexity at least in comprehensible portions. That is, experimental measurement of multiple molecular components (e.g., 'proteomics') and manipulation of molecular components systematically (e.g., 'functional genomics') within a defined cell biology study has become feasible, and the consequent computational analysis required for interpretation of the data has become increasingly accepted by a growing community within the cell biology field. This combination of multicomponent experimental measurement and/or manipulation with computational mining (for hypothesis generation) and/or modeling (for hypothesis testing) epitomizes the area of biological science termed Systems Biology; in relation to cell biology particularly, it can be called Systems Cell Biology. Presenting current state-of-art accomplishments, efforts, and perspectives is the aspired role of Part IV of this Encyclopedia.

Definitions of systems biology range across a wide spectrum as does work in the field itself. Two extremes on this spectrum were offered early on. One was from the Institute for Systems Biology ([Ideker et al., 2001](#)):

Systems biology does not investigate individual genes or proteins one at a time, as has been the highly successful mode of biology for the past 30 years. Rather, it investigates the behavior and relationships of all the elements in a particular biological system while it is functioning.

The other was from the National Institute of General Medical Sciences ([Anderson, 2003](#)):

Systems biology seeks to predict the quantitative behavior of an in vivo biological process under realistic perturbation, where the quantitative treatment derives its power from explicit inclusion of the process components, their interactions, and local states.

As explained in a commentary article elsewhere ([Lauffenburger and Giacomini, 2013](#)), these two definitions respectively focus on aspiration for genome-wide comprehension on the one hand and quantitative prediction on the other, with the two not immediately coincident. A central unifying concept, emphasized in two academic endeavors at MIT (see Relevant Websites section) and Harvard Medical School (see Relevant Websites section), calls for understanding how complex biological entities function by integrating quantitative information about multiple molecular- and cellular-level

components and properties via computational modeling in order to generate hypotheses, predictions, and insights.

The contributions within Part IV are organized thematically by a framework attributable originally to Peter Sorger when he and Douglas Lauffenburger, along with other colleagues, established the Computational and Systems Biology Initiative at MIT shortly after the turn of the millennium. This framework laid out 'Three Dimensions of Biological Systems Complexity,' all of which ought to be fertile ground for address by systems biology ideas and methods. It is illustrated by the diagram [Figure 1](#), reproduced from [Lauffenburger \(2012\)](#).

Efficient description of this diagram can be provided by quoting directly from the cited article:

One axis represents what I would term 'Horizontal Integration', and is the most common view of the field of systems biology: that of moving from the study of individual components to that of multiple components concomitantly. This might focus on molecular machines, or pathways/circuits/networks at a minimal level of non-reductionist complexity, all the way to genome- (or transcriptome-, proteome-, metabolome-, etc) wide extent. A second axis represents 'Vertical Integration', often associated with physiology (whether mammalian or microbial); that of moving from the study of system operation (phenotype, essentially) from the simplest contexts at the smallest space- and time-scales to more complex contexts involving larger space- and/or time-scales. In the mammalian realm, this integration may feature studies of cell-level behavior dependence on molecular properties, tissue/organ-level behavior dependence on cell properties, organism-level behavior dependence on tissue/organ properties, and population-level behavior dependence on organism properties; analogies exist in the microbial realm as well. Clearly, integrating across more than one of these spatiotemporal scale interfaces is an overarching goal, and when experimental studies of this kind are coupled with computational modeling yields the swiftly-growing field of multi-scale modeling. A third axis represents 'Dynamic Integration', characterized by the depth or intensity of information address in measurement and modeling. This axis moves from sequence and structure at the most basic degrees, through thermodynamic information, to kinetic and transport information, to comprehensive dynamical systems operation at the most extreme degree. It thus may be considered to range from bioinformatics to biochemistry to biophysics, as one vein of characterization.

Accordingly, Part IV of this Encyclopedia is organized in three sections along these three dimensions. Jason Haugh has taken responsibility for the section 'Dynamic Integration,' Helen Byrne for the section 'Vertical Integration,' and Rune Linding for the section 'Horizontal Integration.' Each of these sections comprises a good number of strong articles describing particular facets of the given integration dimension.

Figure 1 Framework laying out ‘Three Dimensions of Biological Systems Complexity,’ attributable originally to Peter Sorger when he established the Computational and Systems Biology Initiative at MIT shortly after the turn of the millennium. Reproduced from Lauffenburger, D.A., 2012. The multiple dimensions of integrative biology. *Integrative Biology* 4, 9.

Dynamic Integration

Whereas Horizontal Integration and Vertical Integration approaches seek to broaden the purview of systems biology in distinct ways, dynamic integration focuses on particular processes, usually involving subnetworks of interacting proteins, in mechanistic detail. Dynamic integration is undergirded by the philosophy that physicochemical principles determine and are thus manifest in the kinetics, spatial patterns, and fluctuations of intracellular processes. It follows that our understanding of those principles hinges on our ability to perturb and measure those dynamic attributes at the molecular level; ultimately, hypotheses couched as mathematical models may be tested on a quantitative basis. Receptor and membrane trafficking, signal transduction and metabolic pathways, cell adhesion and modulation of the actin and cytoskeleton, and gene regulation are among the central intracellular processes that have been studied fruitfully using a dynamic integration approach.

All of these areas are represented under the banner of Dynamic Integration in this volume, covered by experts in the analysis and modeling of these systems. Foret, Brusch, and Jülicher ([Theory of Cargo and Membrane Trafficking](#)) review a recently developed theory of cargo and membrane trafficking. Three articles are related to signal transduction: whereas Blüthgen and Legewie ([Dynamics of Protein Kinase Cascades](#)) focus on the dynamics of protein kinase cascades (such as the thoroughly studied Raf–MEK–ERK pathway), the other two discuss how signaling pathways are spatially organized during polarization of yeast (Wedlich-Söldner) ([Cdc42 and the Mechanisms of Yeast Cell Polarization – A Paradigm for Mesoscale Systems Biology](#)) and in gradient sensing by chemotactic cells (Iglesias) ([Dynamics of Gradient Sensing and Chemotaxis](#)). Sauro ([Metabolism](#)) provides an extensive primer on control theoretical analysis of metabolic pathways and networks, which is complemented by the article on gene regulatory networks by Jermusyk and Reeves ([Transcription Factor Networks](#)). On the biophysics of the cytoskeleton, there are two articles: Borinskaya,

Marchenko, and Loew ([Modeling Actin Dynamics](#)) cover the dynamics of actin filaments, whereas Castle and Odde ([Dynamics of Microtubule Self-Assembly](#)) tackle microtubules.

Vertical Integration

Many cellular functions, including proliferation, migration, and gene expression, are regulated by multiple processes acting across multiple spatial and timescales. While mathematical models of the constituent processes can provide insight into aspects of a particular cell function, the models must be combined to provide a more complete understanding of the system. Vertical integration is the merging of models formulated at different spatial and/or temporal scales to produce multiscale models. This article provides an introduction to vertical integration. This section illustrates how multiscale models may be assembled, the insight they may generate and the challenges associated with their development and validation.

The overview article (Byrne, [Vertical Integration](#)) summarizes the mathematical and computational approaches that are used to construct and simulate multiscale models ([Computational Approaches for Multiscale Modeling](#)) and the subsequent articles review the state-of-the-art in applications of multiscale modeling to the heart ([Cardiac Modeling](#)), angiogenesis ([Angiogenesis](#)), morphogenesis ([Multiscale Analysis of Morphogenesis](#)), neurogenesis ([Neurogenesis in the Adult Brain](#)), wound healing ([A Review on Various Mathematical Modeling Approaches for Wound Healing](#)) and inflammation ([Mathematical Approaches to Studying Inflammation](#)). For additional information on the mathematical and computational aspects of multiscale modeling and its biological applications, the interested reader is referred to the following review articles: Bassingthwaite *et al.* (2005), Cvijovic *et al.* (2014), Kohl and Noble (2009), Meier-Schellersheim *et al.* (2009), Schnell *et al.* (2007), Southern *et al.* (2008), and Walpole *et al.* (2013).

Horizontal Integration

In order to respond to alterations in its environment, a cell has to integrate multiple input-cues and modulate its signaling networks ([Understanding of 'Networks' *In Vitro* and/or *In Vivo*](#)) accordingly, in order to elicit a specific response such as proliferation or apoptosis. These processes become significantly altered during cancer development, with genomic modifications giving rise to differential protein dynamics, ultimately resulting in disease. The exact molecular signaling networks ([Interactomes – Scaffolds of Cellular Systems; Phosphoproteomics: Approaches, Developments, and Challenges](#)) underlying specific disease phenotypes remain elusive, as the definition thereof requires extensive analysis of not only the 'omic landscapes' (genomics, [Connecting Evolutionary Genomics to Cell Biology](#); transcriptomics, [Transcriptomics](#); proteomics, [The Advent of Mass Spectrometry-Based Proteomics in Systems Biology Research](#); and metabolomics, [Metabolomics in Cell Biology](#)) within a particular tumor, but also the phenotypic response to perturbations. Additionally, a combination of *in vitro* and *in vivo* models are required, both capturing various aspects of the true biological complexity ([High-Content Screening in Cell Biology](#)). Thus, to obtain a comprehensive understanding of pathological processes, there is a critical need for an integrative global approach, which assesses a biological system such as cancer ([Computational and Systems Cancer Biology](#)) from several molecular aspects in an unbiased fashion ([Network Modeling of Heterogeneous Datasets; Stochastic Analysis of Nongenetic Cell-to-Cell Heterogeneity](#)). Overall, this section aims to demonstrate the value of deploying several genome-scale experimental platforms ([Systematic Methods to Interrogate Genetic Perturbations and Map Phosphorylation-Dependent Signaling; Integrative Systems Biology](#)), each studying a different biological aspect, combined with in-depth computational analysis, in order to shed light on the fundamental molecular processes

which underlie a complex disease like cancer and provide possible avenues for therapeutic intervention ([Drug Targeting](#)).

Introduction

The ability to direct movement based on environmental cues is of paramount importance for the survival of many organisms. In many cases, this movement is in response to chemical gradients, a process known as chemotaxis. However, there are many examples of cells moving in response to other types of external cues, including electrical fields (electrotaxis) and currents (galvanotaxis), light (phototaxis), temperature (thermotaxis), mechanical stress (mechanotaxis), and the mechanical compliance of the substrate (durotaxis) (Eisenbach, 2004). Single-cell organisms, such as free swimming bacteria and ameboid cells, employ chemotactic strategies to search for nutrients or to survive. In multicellular organisms, chemotaxis plays a major role in many aspects of development and tissue maintenance. Normal physiological processes such as lymphocyte homing, angiogenesis, embryogenesis, neurogenesis, wound healing, and sperm activation require accurate migration of specific cells. On the other hand, inappropriate regulation of chemotaxis plays a role in excessive inflammation and inflammation-related diseases such as asthma, multiple sclerosis, and arthritis (Di Gennaro and Haeggström, 2012). Chemotaxis can also lead to deleterious outcomes – for example, metastatic cells employ a chemotactic strategy in their migration away from the primary tumor toward distant organs (Roussos *et al.*, 2011).

Cells performing chemotaxis do so by coordinating a number of separate but interrelated processes. Clearly, chemotactic cells must be motile. The various methods used by cells to move is highly diverse, including swimming by the beating of flagella and cilia, swarming, gliding, crawling, and ameboid movement. While the motility mechanisms are different, a relatively common feature of most chemotactic cells is that they remain motile in the absence of chemotactic stimuli. For example, *Escherichia coli* bacteria swim by continuously alternating between periods of

counterclockwise and clockwise flagellar rotation (Berg, 1993). When rotating in the counterclockwise fashion, the flagella propel the cell. Alternatively, with clockwise rotation, the flagella unbundle causing a short tumbling event – a period where movement stops and the cell's axis is randomly reoriented in space. In the absence of chemoattractant gradients, the expected period between tumbling events is relatively constant, so that movement follows a random walk. Similarly, in *Dictyostelium discoideum* amoebae – a common model organism for studying chemotaxis in eukaryotic cells – actin-rich pseudopodial extensions are projected isotropically along the cell periphery, propelling the cell (Swaney *et al.*, 2010). In the absence of chemotactic cues, the resultant motion has the statistics of a persistent random walk (Li *et al.*, 2008). The nature and timing of these pseudopodial extensions do not differ greatly between randomly moving and chemotaxing cells (Andrew and Insall, 2007). Thus, the external chemoattractant gradient is used not to promote motility, but to align movement in the direction of the chemoattractant gradient. In some cells that use flagellar systems for movement, this direction takes the form of active steering (Fenchel, 2001). In most other cases, however, the alignment results from a stochastic biasing of the migratory apparatus so that, over time, net movement is in the direction of the external gradient. For *E. coli* cells the period between tumbles is modulated so they are less frequent when swimming up a gradient (Berg, 1993). For *Dictyostelium* cells, the location of the pseudopods is regulated so as to move along the gradient (Andrew and Insall, 2007).

Strategies for Chemotaxis

To align the axis of migration with the external chemoattractant field requires a mechanism for sensing the external

chemoattractant concentration – cell surface receptors that are specific to the chemoattractant ligand – and a means for interpreting this signal so as to determine a preferred spatial direction. For the latter, cells broadly employ two different strategies based on temporal or spatial information (Devreotes and Janetopoulos, 2003).

Temporal Sensing

A cell that is moving up a chemoattractant gradient experiences increasing receptor occupancy over time. Conversely, if receptor occupancy is decreasing over time, then the cell must be moving down the chemoattractant gradient. Thus, a cell can determine whether its movement is aligned with the chemoattractant gradient by comparing the level of occupied receptors over time as it moves in a medium (Figure 1(a)). This temporal sensing strategy for determining the concentration gradient is particularly effective if cellular movement is sufficiently fast that the cell can explore a large region in a reasonable time. Organisms that direct movement using a temporal sensing strategy include various free swimming

bacteria such as *E. coli*, which moves at 10–20 body lengths per second. In this case, the temporal changes in the chemoattractant receptor occupancy are used to regulate the timing between run and tumble episodes.

Theoretically, this temporal sensing strategy can be accomplished through differentiation of the chemoattractant receptor occupancy signal. Experimentally, the presence of this differentiation can be tested by measuring the response of cells to a step change in the concentration of the chemoattractant. In the presence of temporal differentiation, except for a short transient following the application of a chemoattractant stimulus, the cellular response should be independent of the stimulus level, as the derivative of a steady signal is zero. This adaptation, or return to prestimulus levels, is a consequence of the temporal differentiation.

In practice, however, perfect differentiation is neither feasible nor desirable. The binding of chemoattractant ligands to their receptors is a stochastic process (Ueda *et al.*, 2001). As such, even in the presence of a constant level of chemoattractant concentration, the number of occupied receptors fluctuates as molecules bind and unbind. Pure

Figure 1 Strategies for determining the chemoattractant gradient. (a) In the temporal scheme, small, fast moving cells compare receptor occupancy over time. When moving down a gradient, the number of occupied receptors will decrease over time. Conversely, as cells move in the direction of increasing concentration, the number of occupied receptors increases. This strategy is used by *E. coli* cells, which move during runs, which alternating with short periods, or tumbles, where the cell is reoriented randomly. Directional migration is achieved by modulating the time between these two states, so that when receptor occupancy is increasing, the period between tumbles is lengthened, and shortened when moving down the gradient. (b) Larger, slower cells use a spatial gradient sensing mechanism. These cells have receptors distributed around the cell perimeter, and can compare the number occupied at different points in space. Directional movement is achieved by localizing the motility apparatus in the region with highest receptor occupancy.

differentiation of this noisy signal would amplify these stochastic fluctuations and this would cause the cell to respond to the noise, rather than the chemoattractant signal. In practice, the period over which the temporal comparison is made needs to be sufficiently long to filter out the effect of these fluctuations (Berg and Purcell, 1977). This can be done by increasing the time over which the temporal comparison is made. In *E. coli*, this comparison is based on the receptor occupancy over 2–4 s. This filtering time cannot be too long, however. Otherwise, the concentration of the gradient may change as the cell is moving. In bacteria, this can be because of the effects of rotational diffusion which prevents the bacteria from swimming in perfectly straight lines. Analysis of the resultant tradeoffs suggest that *E. coli* cells balance these competing requirements by integrating the receptor occupancy information over periods which are close to optimal.

Spatial Sensing

Temporal sensing may not be adequate for slow moving cells, as the level of receptor occupancy will not change appreciably over time. Moreover, the region in space that could be explored would be small. However, if these cells are sufficiently large, so that the chemoattractant concentration at multiple locations can be measured simultaneously and compared, then information about the chemoattractant field can be deduced without movement (Figure 1(b)). This spatial sensing mechanism seems to be preferred by larger, slower eukaryotic cells, including social amoebae and cells of the mammalian immune system.

In *Dictyostelium* cells, chemoattractant receptors and associated G-proteins are distributed uniformly along the cell perimeter (Swaney *et al.*, 2010). In response to chemoattractant gradients, several signaling events are selectively localized. For example, activation of Ras proteins and PI 3-kinase, accumulation of phosphatidylinositol (3,4,5) phosphate (PIP3), and actin polymerization occur at the side of highest chemoattractant receptor occupancy. In contrast, the PI 3-phosphatase, PTEN, and myosin localize at the rear of the cell. These signaling events can be localized in cells that are immobilized by inhibitors of the cytoskeleton (Parent and Devreotes, 1999). When these cells are exposed to a stable gradient, the front and rear responses form crescents toward or away from the high side of the gradient, and these responses persist as long as the gradient is present, thus demonstrating the presence of a spatial sensing mechanism.

For cells in a gradient, the level of receptor occupancy differs at various sites along the membrane. However, to direct movement, the cell must still determine which side of the cell is experiencing greater occupancy. The precise nature by which this comparison is made has been a long standing open question, with a number of models proposed (Devreotes and Janetopoulos, 2003). In theory, pseudopods could be extended at a rate proportional to the local receptor occupancy. In this case the side of the cell facing higher chemoattractant concentration would experience greater number of protrusions, and so net movement would be in this direction. However, the side with lower receptor occupancy would also

see an increase in the number of protrusions relative to an unstimulated cell. In practice, this increase is not seen. Rather, there is a suppression of pseudopod extensions at both the lateral and posterior regions of the cell. Thus, some form of inhibition, which may be due to the presence of an inhibitor, or because of depletion of molecules needed for protrusions, is believed to be active. A general model that has been proposed is the local excitation, global inhibition (LEGI) mechanism (Figure 2; Parent and Devreotes, 1999; Levchenko and Iglesias, 2002). In this scheme, local receptor occupancy triggers both a fast excitation and a slower inhibitory process. The chemotactic response is dictated by the balance between these two processes. Moreover, whereas the excitation signal remains local to where it was formed, the inhibitory signal can diffuse away and hence represents the average level of receptor occupancy. Thus, excitation exceeds inhibition at the site of highest receptor occupancy, leading to a net positive signal. Conversely, at the site of lower concentration, inhibition is higher than excitation and the chemotactic response is suppressed.

Figure 2 Local excitation, global inhibition model for spatial sensing. In the scheme, the external signal, which represents receptor occupancy, regulates a fast, local excitation, and a slow, global inhibitor. Together, these processes regulate in complementary fashion a response regulator that signals to motility. When introduced to a gradient, the side facing the highest concentration has greater number of occupied receptors (gray circles), and hence generates more excitation molecules (green). More slowly, but still following the receptor occupancy gradient, inhibition molecules (red) are formed. These molecules diffuse away from the site of their production, and equilibrate spatially, reflecting the global level of receptor occupancy. Thus, at the side facing the highest chemoattractant concentration, excitation exceeds inhibition, leading to a positive response. At the rear, inhibition is higher, leading to a suppression of the response.

Adaptation in Chemotactic Systems

Though adaptation appears to be a necessary feature of the temporal sensing strategy, it is also found in a number of cells that can sense gradients spatially, such as *Dictyostelium* amoebae and neutrophils. When these cells are stimulated with spatially uniform step changes in chemoattractant concentration, the responses that are usually seen at the front, such as PIP3 accumulation, transiently increase while those that localize to the rear, such as PTEN membrane association, decrease before returning to baseline. Nevertheless, subsequent responses are triggered by increments in receptor occupancy and adapt when occupancy is held constant. Further response only occurs if occupancy is increased again or if the stimulus is removed and reapplied after a period of deadaptation.

Not all chemotactic cells adapt to isotropic chemotactic stimuli, however. For example, the response of migrating fibroblasts to uniform PDGF stimulation does not adapt, though these cells can only respond to gradients over a relatively narrow range of chemoattractant concentrations (Schneider and Haugh, 2005). Thus, part of the advantage of adaptation is that, by filtering out the mean level of chemoattractant concentration, it helps to focus the signal on the gradient. In this case, the resultant movement depends on the relative and not absolute gradient (Zigmond, 1977).

Over the years, a number of mechanisms have been proposed to explain the adaptive behavior of cells. It can be shown, however, that the schemes can be broadly grouped into two classes (Ma et al., 2009). Here we briefly outline minimal models for each of these two schemes.

Adaptation through Negative Feedback Regulation

Negative feedback control is a ubiquitous means for regulating the level of a response. It also forms the basis for several mechanisms proposed to explain the observed adaptation of cells to persistent changes in external chemoattractant stimuli. The basic scheme is shown in Figure 3(a). Here, an external signal S (e.g., chemoattractant receptor occupancy) triggers a chemotactic response: $S \rightarrow R$. Thus, as the concentration of the external signal increases, so does that of the response. Additionally, the scheme includes a regulatory buffer (F) that

Figure 3 Schemes for achieving adaptation. (a) Negative feedback system. In this scheme, the external chemical (S) signals to a response (R). The latter signals to a buffer (F) that closes a negative feedback loop. (b) In the incoherent feedforward scheme, S signals to both excitation (E) and inhibition (I) processes, which regulate in complementary fashion the regulator. Note that the local excitation, global inhibition pathway of Figure 2 is a special case of an incoherent feedforward system.

provides negative feedback from the response back to itself: $R \rightarrow F \rightarrow R$. In this case, as the concentration of the response increases, so does that of the feedback buffer. Eventually, this negative feedback drives the response toward prestimulus levels.

The scheme proposed here is equivalent to an influential model proposed to explain the experimentally observed perfect adaptation in *E. coli* chemotaxis (Barkai and Leibler, 1997). In these cells, the chemoattractant receptor occupancy signal is transmitted to the flagellar motor by protein CheY, which are in turn regulated by CheA, a histidine kinase which forms a complex with the receptors (Wadhams and Armitage, 2004). These complexes are assumed to exist in one of two activity states. Binding of chemoattractants to the receptor alters the state of the receptor leading to changes in the phosphorylation state of CheA, which in turn alters the rotational state of the motor. However, receptor-CheA complexes can undergo reversible methylation at a number of glutamate residues by two proteins: a methyltransferase, CheR, and methylesterase, CheB. The latter is also regulated by the phosphorylation state of CheA, closing a negative feedback loop as changes in receptor methylation level shift restore a balance between counterclockwise and clockwise signal outputs.

In practice, a number of conditions must be met to ensure perfect adaptation – that is, that the response return exactly to the basal level (Yi et al., 2000). In this case, it can be shown that the adaptation mechanism is equivalent to integral feedback control, a common engineering motif used to minimize the effect of disturbances in man-made systems.

Adaptation through an Incoherent Feedforward Scheme

A second class of adapting motifs is described in Figure 3(b). This scheme was originally proposed by Koshland (1977) as a means of explaining adaptation in bacterial chemotaxis though it is now more widely used to explain adaptation in models of chemotactic amoebae (Levchenko and Iglesias, 2002; Tang et al., 2014). This is a special case of the LEGI mechanism described above. As above, the central element of network is a response element, R , that is activated by an excitatory process E , and suppressed by an inhibitory process, I . Both of these regulatory processes are themselves regulated by the stimulus, through increases in receptor occupancy, S . Because the excitation and inhibition signals provide complementary regulation on the response regulator, the motif is sometimes known as an incoherent feedforward loop. The key to achieving sensory detection is that the time scale of the two excitation and inhibition processes be different. If the excitation is faster, then the response rises transiently as excitation increases. As the inhibition catches up, the response eventually subsides to the prestimulus levels.

Signal Amplification and Sensitivity

One of the remarkable features of chemotactic cells is their ability to discern small differences in chemoattractant concentrations and to use this to chemotax effectively. In amoeboid

cells, the difference in chemotactic receptor occupancy between opposite sides of the cell can be as small as 1–2% (Zigmond, 1977). Moreover, the degree to which the external signal is amplified by internal signals, such as PIP3 localization, can be in the order of 7–10 fold, so that a 10% difference in chemoattractant concentration can lead to 70% difference in PIP3 levels (Janetopoulos *et al.*, 2004). In *E. coli*, changes in the order of 0.2% can alter the probability of tumbling by 20%, an amplification of 100 (Sourjik, 2004). Experiments using fluorescent resonance energy transfer demonstrated that the receptor signaling can achieve 35-fold amplification. Moreover, these changes can be detected over a range of background concentrations that ranges over five orders of magnitude. How this signal amplification is achieved is an active area of interest.

Amplification through Receptor Coupling

A number of researchers have suggested that the extreme sensitivity of the bacterial chemotactic signaling system may arise from interactions between two-dimensional receptor clusters. *Escherichia coli* chemoattractant receptors are clustered at both poles of the cells and exist as homodimers, which are then arranged as trimers of dimers (Sourjik and Wingreen, 2012). Models that assume that these receptors act independently do not recreate several observed characteristics, including the signal amplification, as well as integration of various chemotactic signaling cues. However, a number of models have been proposed that suggest that receptors do not work independently, but rather as cooperative clusters, though the specific interactions are not known. For example, receptors could follow the classic Monod-Wyman-Changeux model of multi-subunit allosteric proteins, or they could interact in larger lattices of interacting receptors (Sourjik, 2004). In either case, binding of a ligand to a receptor leads to a conformational spread across the cluster. If the coupling is sufficiently strong, then all receptors in a cluster are found in the same state. These models are able to explain the observed sensitivity.

Amplification through Positive Feedback

A common way to amplify signals is through the use of a positive feedback signal, or its functional equivalent, the double negative feedback loop. The existence of various positive feedback pathways regulating chemotaxis has been demonstrated. For example, in neutrophils, a positive feedback involving PIP3 and actin polymerization has been demonstrated (Van Keymeulen *et al.*, 2006). In *Dictyostelium* cells, a similar pathway exists involving Ras (Sasaki *et al.*, 2007). Measurements of the amplification in *Dictyostelium* cells that have been treated by latrunculin show that the signal gradient amplification is smaller, suggesting that actin does play an active role, but it is still present, indicating that other actin-independent steps must exist (Janetopoulos *et al.*, 2004). Positive feedback loops are also present in the chemotaxis signaling pathway of *Bacillus subtilis*, where it is enacted by suppression of the CheV protein (Rao *et al.*, 2004).

The presence of a positive feedback loop can present some difficulties, as can be attested by anyone who has placed a

microphone near a speaker. Once started, how do you turn off the signal? In fact, positive feedback may also lead to hysteresis, whereby the response of a system depends not only on the present level of the input, but also on the past (Ferrell, 2002). Evidence of this memory exists in the chemotactic responses of both bacteria and eukaryotes. In the latter, it is best observed in cells subject to a change in the direction of a gradient. These cells, which are usually referred to as being polarized, turn gradually in the direction of the new gradient (Devreotes and Janetopoulos, 2003; Skoge *et al.*, 2014; Nakajima *et al.*, 2014). This behavior can be seen as the result of a tradeoff between the immediate gradient sensing mechanism and an internal compass that remembers the past direction (Andrews and Iglesias, 2007).

Even if hysteresis is desirable, the effect of the positive feedback must be limited. For this reason, positive feedback loops are usually counterbalanced by negative feedback loops (Brandman and Meyer, 2008). Coupling these two types of feedbacks may lead to oscillatory behavior.

Amplification through an Excitable Network

Recent years have revealed the presence of excitable behavior in the chemotactic pathways of several eukaryotic cells (Iglesias and Devreotes, 2012). Excitable systems operate at a stable point in which small amplitude perturbations lead to negligible responses. However, if the perturbations are sufficiently large, they can cross a threshold in which a strong positive feedback loop leads to a large scale, transient response, or firing. This is followed by the triggering of a negative feedback loop that eventually causes the response to subside and the system to return to its equilibrium. Evidence for the presence of excitable behavior includes the presence of propagating waves (Vicker, 2002; Weiner *et al.*, 2007) and a refractory period that follows the triggering of the excitable behavior, during which no further firings can take place (Huang *et al.*, 2013; Nishikawa *et al.*, 2014).

The presence of excitable behavior helps to explain how cell motility can be biased during chemotaxis. In unstimulated cells, stochastic fluctuations that arise during molecular events can lead to supra-threshold triggering of excitable behavior, which will lead to actin polymerization and pseudopod protrusions. For cells in a gradient, gradient sensing mechanism can regulate the level of the threshold, so that, compared to unstimulated cells, firings are more likely at the front and less likely at the rear. Thus, threshold regulation can help to bias the likelihood of generating pseudopods between front and back. However, once a pseudopod is triggered, including life time and size, proceeds independently of the external chemoattractant signal.

Conclusions

Chemotaxis is a fascinating biological process of central importance to the survival of organisms. It brings together fundamental properties of cells including the ability to move, to communicate with its environment, and to regulate cell shape. It also is a fascinating example of how biology brings together

design principles that are common in man-made systems, such as positive and negative feedback loops, hysteresis, oscillator, amplification, adaptation, robustness, and redundancy to solve an essential need in diverse and elegant fashion.

Modeling Actin Dynamics

S Borinskaya, O Marchenko, and LM Loew, University of Connecticut Health Center, Farmington, CT, USA

Introduction

Microfilaments, microtubules, and intermediate filaments are the polymers that comprise the cytoskeleton of cells. But the microfilament system, for which actin is the basic building block, is arguably the most complex because of the variety of regulatory mechanisms that control its function and dynamics. The regulation of actin polymerization, bundling, cross-linking, branching, and its association with plasma and organelle membranes, is controlled by an enormous number of signaling molecules and actin-binding proteins. Because of this diverse biochemistry, actin can be utilized by the cell to control diverse physiology, including motility, endocytosis, cytokinesis, morphogenesis, and organelle trafficking.

Given the importance of actin, it has been the subject of intense experimental investigation, as reviewed in the article in this work by Carrier *et al.* These studies include many quantitative measurements both *in vitro* and *in vivo* on the interactions of actin with its regulators. Because of the complexity of these biochemical interactions, it is difficult to understand how the various components work together to produce a cellular behavior. But the wealth of quantitative measurement on these components also offers the opportunity to solve the complexity problem through computational modeling. Modeling addresses the complexity of actin dynamics in two related ways: (1) The construction of a model helps the investigator organize all the diverse experimental data that are used as input to the model and also identify key pieces of information that may be lacking; (2) Simulations can predict the results of new experiments, especially cellular measurements, and thereby test the hypotheses that are inherent to the model. Of course, these advantages of modeling are true for any complex biological system (Slepchenko *et al.*, 2003). But actin dynamics has the additional challenge of requiring the integration of cell signaling, biochemistry, polymer physics, and mechanics.

The wealth of biochemical and signaling data calls for detailed models that aim to address the role of each molecular player in the system. On the other hand, the polymer physics and mechanics have inspired more conceptual models that attempt to explain the global features of the cell biology. The philosophical difference between detailed and conceptual models, as related to actin modeling, has been recently discussed (Ditlev *et al.*, 2013; Mogilner *et al.*, 2012). In this article, we will provide the reader with a guide to examples of each approach to modeling actin dynamics with a view toward illustrating how each approach can produce valuable and complementary insights into this complex but central subject within the field of cell biology.

Conceptual Models of Mechano-Chemical Control of Cell Motility and Shape

Conceptual models of actin dynamics are typically minimal models focused on various biomechanical aspects of cell

motility. These models are based on fundamental laws of thermodynamics and mechanics, specifically, on force balance within the cell cytoskeleton and mass conservation of actin. In the multifaceted space of diverse interacting physical/chemical mechanisms, intuition falls short in the interpretation of the experimental data or prediction of new mechanisms. To generate conceptual models, these mechanisms must be reduced to mathematical equations, containing variables related to experimental observables or parameters that have experimentally controllable correlates; solving these equations through simulations can then generate hypotheses and motivate new experiments on how actin dynamics can be marshaled to propel cells, intracellular organelles, or pathogens. The abstractions and approximations depend on the specific question addressed by each particular model. In this section, we will describe a few examples of how conceptual models have been applied to actin-driven motility and the control of cell shape. However, to stress the mechanistic concepts underlying these models, we deliberately have avoided exposition of the mathematical equations that had to be solved (generally with numerical simulations). We refer the reader to the original papers for these details.

'Brownian ratchet' is a machine that uses the random Brownian motion of molecules to produce work. It may be applied in a model for how actin dynamics can produce membrane protrusion or propel a microbe: thermal fluctuations of the membrane at the tip of a growing filament or bending motions of the filament can make room for insertion of a new actin monomer; subsequent thermal fluctuations allow the process to continue. Since depolymerization is slow, a net protrusive force can be generated. The second law of thermodynamics is upheld because the process extracts energy from hydrolysis of the adenosine triphosphate (ATP) bound to actin.

The possibility that actin filament polymerization at the cell membrane is capable of generating protrusion force was first explained in the 'Brownian ratchet' formalism derived by Peskin *et al.* (1993) for the dependence of polymerization velocity on the effective load size (Figure 1(a)). A study by Mogilner and Oster in 1996 extended this hypothesis by considering the bending fluctuations of the filament; they showed that the velocity is independent of the size of the cargo for situations where the polymerization rate is limiting (i.e., at low monomer concentrations) (Mogilner and Oster, 1996). This demonstrated a fundamental concept that polymerization rate remains largely the same in various actin-driven motility scenarios and also led to models of microorganism motility, such as *Listeria* and *Shigella*.

Discrete versus continuum modeling. The behavior of a cellular process can be fundamentally described in terms of the collection of

Figure 1 Model types and their evolution. (a) The concept of force generation at the cell membrane by self-renewing polymer was first modeled and tested using the Brownian ratchet formulation in studies by Peskin *et al.* (1993) and Mogilner (Mogilner and Oster, 1996). (b) Further experimental evidence lead to a rigorous utilization of actin network as force generating unit with viscous and/or elastic properties (c). Finally, continuum models were developed to look into full-scale models of how the actin network can generate cell locomotion (Wolgemuth *et al.*, 2011).

discrete probabilistic events occurring at the molecular level; such models have the advantage of correctly describing the stochastic variability of systems with small numbers of molecules. However, discrete models may be complex, computationally intractable, or fail to provide understanding of the emergent behavior of the system. Continuum modeling describes the system in terms of changes in concentrations or densities of molecular species and solves ordinary or partial differential equations (ODEs or PDEs) to predict the average system behavior. ODEs describe just the rate of change of all 'species.' PDEs add the motion of the species within a spatial geometry. Because continuum models are deterministic and cannot account for stochastic behavior, they are fundamentally approximate, but they can provide insights on the collective emergent behaviors of complex systems.

The treatment of the actin filament as an elastic spring launched a new generation of models that use familiar mechanical components to describe actin network flow and deformation: springs, dashpots, and motors (Figure 1(b)). Myosin motor activity and its effects on actin polymerization are considered in such models. The differential treatment of G- and F-actin anticipated the two-phase treatment of the cytosol which led to development of 'continuum models' that incorporate contractile stress, polymerized actin, and cytosol flow with traction forces on the whole cell scale (Danuser *et al.*, 2013; Figure 1(c)).

Species. A biological molecule (ligand, second messenger, drug, protein, DNA, RNA, etc.) or a particular state of a molecule (e.g., monomer or dimer, phosphorylated or unphosphorylated, adenosine diphosphate (ADP)-bound actin or ATP-bound actin). It can also be used in relationship to any other player (e.g., fluorescently labeled protein) in the experimental system to be modeled. Each species corresponds to a variable in the model.

Mogilner and Oster's Brownian ratchet model (Figure 2) demonstrates that polymerizing actin filament can generate protrusive pressure and push the membrane, which results in cell motility. Relaxing the assumption that the filament is rigid and also considering cross-linking as well as parallel filaments, they construct a statistical mechanical model of *Listeria monocytogenes* movement and lamellipodial protrusion. For the sake

Figure 2 Elastic actin filament in Brownian ratchet model (Mogilner and Oster, 1996).

of simplicity the study ignores cytoplasmic fluid flow. Actin filaments are modeled as elastic rods with persistence length $\lambda = 1 \mu\text{m}$ that grow by addition of monomers at rate $k_{\text{on}}M$ and shorten at rate k_{off} .

The model predicts that with an increase in the resistance force, the filaments of the lamellipodial cytoskeleton will align at angles more parallel to the leading edge of the cell. Higher concentrations of actin-binding proteins would produce heavier cross-linking, shorter free ends of the filaments, and effectively slower protrusion velocities. The model concludes that lamellipodial protrusion is driven by polymerization of the thermally fluctuating actin filaments, and the orthogonal geometry of the filaments is determined by actin cross-linking proteins (Mogilner and Oster, 1996). Finally, the model derives an expression for velocity at the membrane, which is then used as a boundary condition to successfully model retrograde flow in fish keratocytes, a cell that glides along a flat substrate without significant changes in shape (Mogilner and Oster, 1996).

The ability to model movement of a cell with a complex shape, such as the fibroblast or neutrophil, is more challenging. Furthermore, the interaction of the cytoskeleton with the rapidly deforming cell membrane and stresses that it generates are complex due to the two-phase nature of the intracellular environment itself. To tackle these challenges Dembo and colleagues developed a continuum model of the contractile and viscoelastic cytoplasm that considers a two-phase treatment of the cytosol and cytoskeleton components

and their interaction with the cell membrane (Herant *et al.*, 2003). To understand which component, fluid or solid, plays a major role in cell shape and locomotion, they develop two hypotheses for the active force generation on the cell membrane: 'cytoskeletal swelling force model' and 'polymerization force model.'

The model equations describe the relations between cytoplasmic flows, substrate adhesion and protrusion dynamics. In the 'network swelling model,' a predominantly fluid system, the cytoskeleton is defined as a disorganized structure with isotropic properties that is continually recycled. In the 'polymerization force model,' the cytoskeleton is viewed as a more permanent, organized scaffolding that allows for the directional production of force. The main idea is that the free energy released by the addition of monomers to a filament is transferred to generate pressure against a membrane. To test the models against the experimental data available, they simulate three classic neutrophil experiments: a neutrophil is passively aspirated into a micropipette, neutrophil exposure to a stimulus triggers the pseudopod extension, and a neutrophil migrates inside a micropipette toward a chemoattractant (Herant *et al.*, 2003). The results include derivation of the three characteristic parameters of the cell cortical properties: baseline tension, slack, and dilation viscosity (Herant *et al.*, 2003). These parameters are constrained by data from aspiration experiments and yield appropriate results for the pseudopod experiments.

Both swelling and polymerization force models create a unifying framework for the experimental data for the three experiments. However, force production required in the polymerization model is beyond what is expected from a simple short-range Brownian ratchet model. In the crawling of neutrophils or other ameboid cells inside a micropipette, Herant *et al.* (2003) argued that measurement of velocity versus counter pressure curves could provide a determination of whether cytoskeleton–cytoskeleton interactions (such as swelling) or cytoskeleton–membrane interactions (such as polymerization force) are mainly responsible for active protrusion. They subsequently analyzed such data and showed that the experiments favor the network swelling model (Herant *et al.*, 2006). The model concludes that local area-increasing shape changes to regulate the membrane cortical tension and overcome a 'dilation viscosity' to produce a pseudopod.

A subsequent study further investigates how membrane tension and polymerization determine shape in 3D cells migrating along a 2D planar substrate (Herant and Dembo, 2010). They showed that changing a few parameters could alter the shapes of migrating cells from the hand mirror shape characteristic of fibroblasts to the half-moon shape characteristic of keratocytes. For fibroblast, the authors approximated adhesion in the boundary conditions as forming immediate attachment at the front edge and detaching at the rear when a threshold force is attained. During migration, fibroblasts displayed drip-faucet instabilities upon tail elongation. Keratocytes were modeled within the same overall formalism, but using weak adhesion and rapid recycling of actin from the rear to the front. One missing piece in the Herant and Dembo models is myosin contractility. Importantly, experimental evidence about the role of myosin contractility in determining

Figure 3 Phase microscopy image of the fish keratocyte cell (Keren *et al.*, 2008).

shape and motility is conflicting and cannot be addressed within the Herant–Dembo framework.

The fish keratocyte has been a popular choice to study the importance of adhesion and myosin contractility in motile cells because it is easily harvested from goldfish scales and the key parameters controlling motility and shape are readily experimentally manipulated. When placed on a flat surface, keratocytes assume a stereotypical half-moon shape with a broad, flat, motile appendage (Figure 3), the lamellipodium. Furthermore, their gliding motility simplifies some of the modeling challenges (Allard and Mogilner, 2012; Barnhart *et al.*, 2011; Rubinstein *et al.*, 2009; Wolgemuth *et al.*, 2011). Their unique ability to maintain nearly constant cell shape, speed, and direction over many cell lengths makes them a perfect system for studying actin-based cell motility.

We focus on a study by Wolgemuth *et al.* (2011) that uses moving-boundary simulations to model cell-shape dynamics and understand how four seemingly redundant mechanisms that may underlie cell motility can determine cell shape and locomotion. Previous models of cell motility considered are schematic, focusing on one mechanism, or complex, with many pathways lumped together. Wolgemuth's study proposes that the redundancy in biochemical and biophysical mechanisms is necessary for robust cellular migration.

The study analyses four distinct minimal mechanisms that regulate cell shape and locomotion: (1) a G-actin transport-limited motility (Figure 4(a)); (2) a motility model limited by microtubule-based transport of vesicles to the leading edge (Figure 4(b)); (3) Rac/Rho-regulated motility (Figure 4(c)), and (4) myosin contraction-driven motility (Figure 4(d)). Using keratocyte cell shape as a template, the study examines if the models, alone or in combination, can produce the half-moon keratocyte shape and the main features of its locomotion at steady state. In all models F-actin flow inside the keratocyte is directed to the cell rear and inward at the cell edges. Once it reaches the cell body at the rear, F-actin is depolymerized. One of the key requirements for all models is that the cell area remains constant. The cell shape is allowed to evolve from an initial circular disc using a moving-boundary algorithm for numerical simulations (Wolgemuth and Zajac, 2010). The authors then assess whether and with what parameters each model evolves the system to the characteristic half-moon gliding phenotype.

Figure 4 Schematic overview of the four locomotion mechanisms tested (Wolgemuth *et al.*, 2011). (a) G-actin transport model's main assumption is that diffusion of G-actin from the cell rear, the F-actin disassembly hotspot, is the limiting step in cell motility. The green ellipse denotes the area where no polymerization takes place, while G-actin assembles at the highest rate at the sides and periphery of the cell. (b) Vehicle transport model tests the assumption that the flux of membrane vesicles to the cell periphery is the rate-limiting step for membrane protrusion and depends on the density of the microtubule ends located at the membrane. (c) Experimental evidence on cell motility regulators Rac and Rho is tested in Rho/Rac model. Rac activation increases actin polymerization area and triggers formation of lamellipodia and membrane ruffles. The model implements activation of actin polymerization where Rac is activated. On the other hand, Rho activation favors F-actin disassembly by activating contractility. (d) The actomyosin contraction model assumes contractile stress is isotropic and proportional to bound myosin, which can bind and unbind. The cytoskeleton is treated as a viscous fluid. Actin polymerization rate is inversely related to the concentration of bound myosin.

G-actin transport is essential for maintenance of the F-actin assembly at the cell sides and leading edge. Thus, the model of Figure 4(a) assumes an initial condition with the highest rate of actin polymerization taking place at one end of the cell and a depolymerization zone at the other end. The hypothesis is that diffusion of G-actin from the cell rear, where it is generated by depolymerization, to the front, where it is needed for polymerization, is the limiting step in cell motility. The model reproduces the keratocyte half-disc shape with rates for actin disassembly/assembly being the two governing parameters. Interestingly, the velocity is nearly independent of the actin polymerization rate. Since cell-front advancement is proportional to the polymerization rate and G-actin is depleted proportionally to the F-actin polymerization, the two processes compete with each other. Thus, cell speed is controlled by the actin disassembly rate, which was reported in live cells (Cramer, 1999). The microtubule transport model, which posits that membrane cycling through microtubule driven vesicle transport is the critical mechanism (Figure 4(b)), also produces a robust shape, which is more 'fan-like' but still roughly fits within the range of morphologies sampled by live keratocytes; area conservation (i.e., a fixed volume of cytoplasm in these 2D models) is essential for this mechanism to work. In contrast, the Rac/Rho model (Figure 4(c)), where

active Rac promotes polymerization at the front and active Rho promotes contractility at the rear, only produces a stable half-moon steady-state geometry if the initial circular geometry is allowed to evolve without imposition of a fixed 2D area.

The myosin contractility model (Figure 4(d)) treats the binding of myosin to the actin network explicitly, along with actin polymerization/depolymerization. The main assumptions are: the actin cytoskeleton behaves like a viscous fluid with viscosity η and myosin exerts an isotropic contractile stress on the actin network that is proportional to the local concentration of bound myosin. Unbound myosin diffusion is rapid enough to consider the unbound myosin concentration uniform throughout the cell. Finally, the polymerization rate is decreased with increasing myosin concentration. Interestingly, the actomyosin contraction mechanism alone fails to reproduce the steady-state keratocyte morphology or motility, although the characteristic half-moon shape and gliding motility seem to be stable for long periods with certain parameter combinations. However, coupling the Rac/Rho mechanism with actomyosin contractility does robustly recapitulate keratocyte morphology and behavior. Actin polymerization rate was assumed to be proportional to Rac concentration and myosin contractile stress was proportional to Rho activation.

Notably, the combined model gives rise to oscillations of the cell front without changes to the cell velocity, providing a possible explanation to experimental observations reported earlier (Barnhart *et al.*, 2011).

In this Section, we have sampled the diversity of biophysical mechanisms that have inspired conceptual mechano-chemical models of actin-driven motility. The control of cell motility and shape fascinate both experimentalists and theoreticians, motivating the design of these conceptual models. However, while some mechanisms or combinations of mechanisms appear to be emerging, further attention to cells other than keratocytes or to other types of actin-driven cell behaviors (e.g., endocytosis, microbe motility, and morphogenesis during cell differentiation) is required. Furthermore, the majority of models address experiments for cells grown on a flat surface rather than a more realistic 3D extracellular matrix with its own rheology and adhesion properties. And finally, none of these models address how a multitude of identified actin-binding proteins and signaling systems regulate actin dynamics. To address the latter class of problems, more detailed biochemical kinetic models are required.

Detailed Biochemical Modeling

The biochemistry underlying lamellipodial actin dynamics is extremely complex. Despite their multiple benefits, conceptual models are not meant to capture the biochemical mechanisms involved in actin cytoskeleton dynamics. Molecularly explicit mathematical models, or as we call them here detailed biochemical models, aim to simulate the interactions of any or all of the many proteins that orchestrate spatio-temporal dynamics of actin polymerization. Such models, when combined with experimental studies, serve as invaluable tools for elucidating the function of individual molecules or collective behaviors within a complex biochemical system. An ultimate goal of this approach may be to identify therapeutic targets and strategies. Detailed models also may offer the opportunity to address questions that are not feasible experimentally. Such ‘In silico’ biochemical simulations can generate new predictions and hypotheses to develop and direct future experimental studies. Detailed biochemical models of a complex reaction network also serve as knowledge integration platforms through which information about a physiological system can be easily shared, updated, enriched, reused, and adapted for another experimental or modeling study. We recently published a short perspective on the benefits of detailed models with a particular application to actin dynamics (Ditlev *et al.*, 2013).

In silico. In biology the term indicates experimentation using computational or mathematical model to test or generate hypotheses or make predictions about behavior of a biological system. Virtual experiment – simulation of a model with a particular set of initial conditions, parameters, and geometry.

To begin thinking about the basic principles underlying polymerization, it would be a useful thought exercise to

imagine that you have attached one link (the nucleator or seed) to a wall and then attach more links one by one at your pace (rate) to form a chain (polymer). The total assembly rate (number of links added per unit of time) for your chain is defined by your pace. Next, you might have more people who would like to engage in this activity and you provide them with the nucleator links. Let’s assume they work at about the same pace as you. We are interested in the total rate of assembly (total increase in the number of links in all the chains). If you had one more person working with you, the total assembly rate would be twice your rate; if you had nine more people the total rate would increase to 10 times your rate. Alternatively, think about the situation where you do not provide other people with the nucleators, but just want them to share access to your single chain. Then everyone will be adding the links to just one chain end and the total assembly rate will not increase. This situation is analogous to polymerization of actin monomers at the barbed ends. The more available barbed ends there are in the system the higher the assembly rate will be – the polymer ends serve as ‘catalysts’ of the assembly process. As we noticed in the example with the chains, the assembly rate linearly depends on the number of starters (number of barbed ends in case of actin polymer). Of course, this depends on an ample abundance of links to the crew you have charged with building the chains (i.e., that the availability of G-actin is not limiting). The same is true for the disassembly rate; the more available pointed ends there are the higher the disassembly rate will be. In order to coordinate this process in space and time the cells have an abundance of actin regulatory proteins which can control availability of filament ends, nucleation, elongation, branching, filament length, bundling, and turnover.

We will first briefly describe the major steps and components of the actin polymerization cycle. The process of actin filament treadmilling (Figure 5(a)) lies at the heart of the actin cycle. Broadly speaking, treadmilling refers to the steady-state polymerization at one end of a filament matched by an equal rate of net depolymerization at the other end; if the system is not at steady state, the filament may grow or shrink depending on which rate dominates. An individual actin monomer (G-actin) cycles through a series of biochemical events: (1) addition of ATP-bound G-actin at the barbed (growing or plus) end of F-actin, (2) hydrolysis of ATP on an F-actin subunit to generate to ADP-Pi-actin, (3) release of Pi from the ADP-Pi subunit, (4) dissociation of ADP-G-actin from the pointed (minus) end, and (5) nucleotide exchange of ADP-G-actin to recharge the monomer into the ATP-G-actin form. Profilin catalyzes the last step of ADP for ATP exchange on the actin monomer so that it may enter the next round of polymerization. Polymerization (Figure 5(b)) is stimulated by the nucleation-promoting factors (NPFs) associated with the inner side of the plasma membrane. NPFs are spatio-temporally regulated and in their active state induce branched (by activating Arp2/3 protein complex) or linear (by activating formin proteins) polymerization of actin filaments. Polymerizing filaments are proposed to push plasma membrane of motile cells by the elastic Brownian ratchet mechanism (Mogilner and Oster, 1996; Peskin *et al.*, 1993) as discussed above. A pool of monomeric actin that is necessary for assembly at the barbed ends is maintained by the buffering activity of thymosin- β 4.

Figure 5 (a) The treadmilling process. Actin monomer undergoes repeated cycle of assembly, ATP hydrolysis, Pi dissociation, disassembly, and nucleotide exchange. (b) Actin dendritic nucleation mechanism. The cartoon depicts several major biochemical processes underlying dendritic nucleation: N-WASP induced Arp2/3 activation and branching, filament treadmilling, cofilin-mediated severing, profilin-mediated ADP/ATP exchange on G-actin, capping of barbed ends, incorporation of ATP-G-actin at the barbed ends, and disassembly at the pointed ends. Adapted from the original cartoon from Pollard, T.D., Borisy G.G., 2003. Cellular motility driven by assembly and disassembly of actin filaments. *Cell* 112, 453–465.

Capping proteins (Caps) terminate growth of the barbed ends. Actin filaments can be destabilized by depolymerization at the pointed ends and by fragmentation into shorter filaments. There are also mechanisms that stabilize filamentous actin by protecting it from depolymerization and fragmentation.

Early work, before the availability of much kinetic data, derived mathematical models based on the thermodynamics of polymer formation (Oosawa and Kasai, 1962). These early modeling studies resulted in discovery of the critical concentration (above which polymerization occurs in solution) of G-actin (Oosawa *et al.*, 1959) and the treadmilling

phenomenon where polymerization depends on the nucleotide state of actin monomers (Wegner, 1976). Subsequently, an increasing amount of quantitative data related to multiple aspects of actin polymerization made development and validation of detailed biochemical models possible (Ditlev *et al.*, 2013).

Bindschadler *et al.* (2004) built a first comprehensive model of the actin cycle that couples ATP-hydrolysis with actin treadmilling. This is an ODE model that predicts the complete steady-state nucleotide profile (Figure 6(a)) within the filaments and demonstrates that Pi release from ADP-Pi increases

Figure 6 (a) Nucleotide state profile. Simulation results from (Bindschadler *et al.*, 2004) showing fractions of ATP-bound (red curve), ADP-Pi-bound (orange curve), and ADP-bound (yellow curve) monomers along 370-subunit long ($1\ \mu\text{m}$) filaments. (b) Schematic of actin cycle. Mechanisms included in a model by Bindschadler *et al.* (2004). (c) Actin branching near bacterial surface. A simulation video frame from (Alberts and Odell, 2004) showing a branched actin filament attached (via ActA) to a surface of *L. monocytogenes*. Collisions of filaments with the bacterial surface produce force propelling the bacterium in the cytosol of the host cell.

the rate of actin filament treadmilling. Essentially this is a model of actin filament assembly and disassembly from purified actin and its key regulatory proteins (Figure 6(b)): ‘explicitly’ modeled profilin and $\beta 4$ -thymosin and ‘implicitly’ modeled barbed-end and pointed-end cappers and cofilin. A year later Vavylonis *et al.* (2005) built a nonsteadystate ‘discrete’ model using kinetic Monte-Carlo simulations based on experimental data (Fujiwara *et al.*, 2002; Kuhn and Pollard, 2005). Eventually the model was validated and refined through experimental observations of individual actin filaments by total internal reflection fluorescence (TIRF) microscopy (Fujiwara *et al.*, 2007). This process of model construction originating from the available experimental data, going through model modifications to fit that data, and eventually making predictions that can be verified experimentally, exemplifies how modeling and experiment synergize.

Explicitly modeled refers to a molecular species that has a specific variable assigned to it in the model description. Implicitly modeled refers to a species that is not defined with a variable but rather with an expression that describes its effect on the system behavior.

An example of a detailed discrete model that tracks individual filaments is a dendritic nucleation model by Schaus and Borisy (Schaus *et al.*, 2007). It is a stochastic 2D computer model that allowed investigation of filament self-organization patterns at the leading edge of the lamellipodial protrusion. The model is based on the ‘dendritic-nucleation/array-treadmilling’ (Figure 5(a)) mechanism and incorporates (1) spatially discretized G-actin diffusion, (2) Monte-Carlo filament kinetics, and (3) elastic behavior of the filament and the membrane. Branching was restricted to the region within 5.4 nm from the plasma membrane while barbed ends were protected from capping in this narrow area. Irrespective of initial filament orientation, the filaments self-organized to

form a branched network with the filament orientation angle of $\pm 35^\circ$ consistent with electron microscopy observations. The system tends to increase the capping rate for the larger angles rather than increasing the branching rates for the smaller filament orientation angles. The authors demonstrated that protection from capping in the 5.4 nm zone was critical for reproducing realistic dendritic actin pattern while branching localization was not required. Membrane flexibility did not affect pattern orientation significantly. However, filament orientation angle was very sensitive to the increase in the filament bending stiffness resulting in a different angle distribution ($70/0/-70^\circ$). This comprehensive discrete model brings to light the idea that experimentally observed self-organization of the dendritic network in the lamellipodium emerges from the essential dynamic properties of the network.

Alberts and Odell (2004) constructed a large hybrid discrete-continuum model of dendritic actin nucleation to reconstitute the motility of *L. monocytogenes* *in silico*. *Listeria* is an intracellular rod-shaped bacteria that hijacks the actin cytoskeleton of the host cell for assembly of the actin comet tails. The comet tails propel the bacteria within the cytoplasm and into the neighboring cells causing the infection to spread. The model combines biochemistry and mechanistic aspects of actin-based motility of *Listeria* that presents then NPF ActA on its surface to activate the Arp2/3 complex in the host cell. An Arp2/3-dependent dendritic nucleation scheme (Figure 6(c)) encompasses biochemical events of the model. Actin monomers and actin-binding proteins are described continuously with reaction-diffusion equations (characterized as protein concentrations). Interactions of continuous players with each other and with individual actin filaments (discrete components) are defined deterministically. Filaments are modeled stochastically meaning that probability (not concentration) of binding/dissociation of each individual filament is computed at each time-step. The growth of a filament depends on the state variables that keep track of location, orientation, and biochemical state of that filament. Various forces act on the simulated bacterium; (1) link force of ActA protein holding a

filament and the bacterium together, (2) collisions of filaments with the bacterium push them apart, (3) Brownian forces with random orientations act on filaments and on the bacterium. The model reproduces the gross qualitative behavior of *L. monocytogenes* with respect to the average speed, persistence of motion, and comet tail morphology. Additionally the simulated bacterial trajectories exhibit the small-scale saltatory (repeated runs and pauses) motion observed by experimentalists. Alberts and Odell used their model to investigate the nature of *Listeria* nano-saltatory motility and concluded that pauses correlated with the Brownian motion and coordinated breakage and formation of ActA links between filaments and the bacterium. The 'in silico reconstitution' allows exploration of bacterial actin-based motility mechanisms. However it was extremely computationally expensive and required 80 Linux processors to solve thousands of differential equations.

Besides Arp2/3, cells have other nucleators of actin polymerization. One class of nucleators consists of various formin proteins (Paul and Pollard, 2009; Pring *et al.*, 2003; Pruyn *et al.*, 2002). They induce formation of unbranched actin filaments in filopodia, polarized actin fibers, cytokinetic ring, and stress fibers. Formins associate with the barbed ends of actin filaments and stimulate elongation while being processively attached to the growing ends. Highly conserved C-terminal FH1–FH2 domains of formin are key players in this process. A doughnut-shape dimer of FH2 domains forms a ring around the barbed end and an unstructured FH1 domain has multiple profilin-binding sites and therefore delivers profilin–actin complexes for F-actin assembly. Using available experimental data (Kovar *et al.*, 2006), Vavylonis built a stochastic comprehensive model (Vavylonis *et al.*, 2006) of FH1–FH2-dependent actin polymerization. The FH1 domain recruits profilin-G-actin from the cytosol. Since FH1 has many profilin-binding sites the concentration of profilin-actin near the barbed end increases. Flexibility of the FH1 domain allows for rapid collisions between profilin and the barbed end to occur. The collision results in a transfer of profilin-actin to the barbed end if the FH2 domain is in the open state. When the FH2 domain is in the closed state, it prevents actin subunit addition. Based on this mechanism, simulated elongation rates were consistent with the experimental rates for four different formins (Kovar *et al.*, 2006). The model showed that with optimal profilin concentration, a maximal elongation rate can be higher than elongation of actin alone. However, high profilin concentration inhibits elongation because profilin outcompetes profilin-bound actin from FH1 domain.

With that historical background, we now turn to a comprehensive and extensible continuum deterministic model developed in our lab: 'An open model of actin dendritic nucleation' (henceforth referred to as the Open Model) (Ditlev *et al.*, 2009) that is currently the most comprehensive mechanistic model of actin dynamics. The Open Model is implemented in the Virtual Cell software system (VCell) (Cowan *et al.*, 2012; Resasco *et al.*, 2012; Schaff *et al.*, 1997; Slepchenko and Loew, 2010). VCell is a computational environment for modeling and simulation in biology that is designed for both experimentalists and theorists. It has a convenient graphical user interface for formulating a model: defining compartments and their geometries as well as molecular players and their

interactions. Both deterministic and stochastic simulations for either 'compartmental' or 'spatial' models can be run in VCell. Models can include molecular reaction–diffusion–advection (flow), membrane fluxes, and can solve the corresponding 'ODEs' or 'PDEs' or stochastic equations for any cellular geometry. VCell offers a variety of data visualization tools: graphs, kymographs, images, export options to spreadsheets, images, and movies. Importantly, it is built on a database, so scientists can access public models and adapt or extend them for their own research.

Compartmental model. Model of a system in which all the species are well-mixed and therefore variables are changing only in time. The system geometry may be approximated by considering the relative volumes and surface to volume ratios of membrane enclosed compartments. The equations may be described by a set of ODEs that include not just reaction kinetics, but also fluxes between compartments or between a volumetric compartment and an adjacent membrane. For systems with small numbers of molecules, reaction probabilities can be treated with stochastic simulations

Spatial model. Model of a system in which the species are distributed in space and undergo transport and/or diffusion processes within explicit geometries. Described by a set of PDEs for deterministic simulations or by combined reaction probabilities and Brownian dynamics for stochastic simulations.

The Open Model (Ditlev *et al.*, 2009) was developed in an effort to account for the key regulatory proteins and mechanisms governing actin dynamics. It builds upon all the mechanisms simulated in the Bindaschadler *et al.* (2004) model and expands the latter with Arp2/3 activation by N-WASP at the membrane, Arp2/3-mediated side branching, regulation of actin dynamics by cofilin, and fragmentation and annealing of actin filaments. The molecules that are explicitly included in the model are actin, a NPF in the membrane (ex. N-WASP), Arp2/3 complex, Cap, profilin, ADF/cofilin, thymosin- β 4, and various associations of actin with ATP, ADP-Pi, and ADP. Despite such a short list of molecular players the model required 60 species and 155 reactions to capture the core mechanisms driving actin dendritic nucleation. In Figure 7(a), the blue rectangles, which overlay the corresponding regions of the reaction network, summarize the mechanisms that are explicitly defined in the Open Model. The model and the simulation results are publicly available through the Virtual Cell database. The simulations can be run on any geometry and therefore facilitate virtual experiments incorporating specifying initial molecular distributions, diffusion, and advection in realistic geometries extracted from microscope imaging data. The Open Model actually contains many such virtual experiments, with different initial conditions, system geometries, and boundary conditions; in this sense, it is actually a collection of mathematical models all examining aspects of a common set of basic biophysical mechanisms.

Figure 7 An Open Model of actin dendritic nucleation (Ditlev *et al.*, 2012). (a) Reaction diagram from Virtual Cell. Green circles – species. Yellow ovals – reactions/transformations. Reactions occurring at the inner side of the membrane *in vivo* are placed in the ‘plasma membrane’ compartment. Membrane reactions can recruit cytosolic species. Each rounded rectangle with a mechanism label points to a set of reactions involved in the indicated mechanism. (b) Nucleotide state tracking. Nucleotide states of the barbed end (red ball outlined in black) and pointed end (yellow ball outlined in black) are explicitly modeled. The states of all the subunits in the interior of the filament are modeled implicitly (state of each subunit is unknown) by three state variables FAT, FAD-Pi, and FAD (concentrations of all the ATP-, ADP-Pi, and ADP-bound subunits respectively). The state of the newly formed pointed end (after the yellow ball outlined in black dissociates) is incorporated into the dissociation rate. (c) Realistic 3D geometry of a protruding cell. Polymerization is triggered by ActiveNWASP (color coded) at the tip of the lamellipodium (7246 molecules). (d) Simulation results from spatial model with Arp2/3 activation. Minimum (blue value) and maximum (red value) are provided for each variable. (e) Interplay of cofilin and Cap. Model predictions for the total amount of F-actin under varied cofilin and capping concentrations. At low capping level increasing cofilin results in F-actin decrease. At high capping level increasing cofilin results in F-actin decrease. (f) Sharp transition from assembly to disassembly $1 \mu\text{m}$ from the leading edge. (Upper) Simulation results (bottom xy slice) from 3D model showing assembly (white) and disassembly (color coded) rates. (Lower) Abundance of barbed and pointed ends across the lamellipodial tip.

The core of the Open Model is the treadmilling of actin filaments. All the events that accompany and drive this phenomenon are depicted in the cartoon in [Figure 5\(a\)](#). This and many other schematic representations of actin treadmilling grossly oversimplify the actual process. [Figure 5\(a\)](#) shows that monomers in the ATP form add to the barbed ends and dissociate in the ADP form at the pointed ends of the filaments. The situation *in vivo* is more complex: monomers in all the states (ATP, ADP-Pi, and ADP) may bind to and dissociate from either barbed or pointed ends of the filaments. Suffixes T, Dpi, and D are used in the model to indicate the nucleotide state of actin ‘species’. The model accurately captures complexity of the treadmilling process with the mechanisms for tracking the nucleotide state and the processes occurring at the barbed and pointed ends (barbed- and pointed-end turnover).

Some of the aspects of cytoskeletal dynamics are difficult to model explicitly. For example, tracking the nucleotide state of each monomer within the filaments could drastically increase combinatorial complexity of the model. Therefore, the nucleotide state is modeled explicitly only at the barbed and pointed ends, resulting in six variables: three states (T, DPi, and D) for each of barbed and pointed end of the filament. The states of all the actin monomers in the interior of the filaments are described implicitly by three state lumped variables FAT (F-actin in ATP form), FAD-Pi (F-actin in ADP-Pi form), and FAD (F-actin in ADP form) ([Figure 7\(b\)](#)). The FAT in the filament undergoes hydrolysis ($\text{FAT} \rightarrow \text{FAD-Pi}$) and then inorganic phosphate dissociation ($\text{FAD-Pi} \rightarrow \text{FAD} + \text{Pi}$). Hydrolysis and Pi dissociation reactions are modeled explicitly and are applied to all the actin species (not only F-actin) in the reaction network.

The six variables that track the nucleotide states of barbed and pointed ends depend on the hydrolysis and phosphate (Pi) dissociation and on the association and dissociation of actin monomers in different nucleotide states. For instance, there are 18 reactions characterizing interactions of monomers with the barbed ends: three types of barbed ends reacting with G-actin in three states as well as with profilin-bound G-actin in three states. Dissociation events of monomers from the ends presented the difficulty of assigning a nucleotide state to the newly formed end (after a monomer dissociates). The monomer next to the explicitly tracked pointed end can be in any of the three nucleotide states because it was implicitly modeled ([Figure 7\(b\)](#)). The model assumes, therefore, that the nucleotide states at this penultimate position will have approximately the same fractional distribution of states at the ends. This assumption was applied to define dissociation rates of actin monomers from various types of barbed and pointed ends.

Actin filaments (F-actin) were shown to undergo the process of end-to-end annealing experimentally ([Andrianantoandro et al., 2001](#); [Sept et al., 1999](#)). Similarly fragmentation of F-actin was demonstrated to be a critical mechanism underlying actin dynamical behavior ([Berro et al., 2010](#); [Schmoller et al., 2011](#)). The annealing and fragmentation were treated as forward and reverse reactions in the Open Model reaction network ([Ditlev et al., 2009](#)). There are nine forward reactions: pointed ends in three states can anneal to the barbed ends in three different states. The rate of annealing reaction decreases as the length of the fragment increases. Additionally annealing

rate expression is scaled by a factor of $(1 - \text{BrF})$ in order to reduce the rate by the fraction of filaments containing branches. The filaments with high BrF (branch fraction) diffuse more slowly and therefore are unlikely to undergo annealing. BrF is determined as the sum of all species where Arp2/3 is bound to FA (i.e., branches) divided by the total concentration of filaments (i.e., half the concentration of all ends).

Cofilin is an essential actin-binding protein that can stabilize as well as destabilize individual actin filaments and the actin network. We will address the overall physiological effects of cofilin on actin dynamics later during discussion of the results of the model. Kinetics and thermodynamics of cofilin-actin interaction are well characterized experimentally ([Blanchoin and Pollard, 1999](#); [Cao et al., 2006](#); [De La Cruz, 2009](#); [Elam et al., 2013](#)) and have been modeled ([De La Cruz and Sept, 2010](#)). The Open Model has a simplified mechanism of cofilin interaction and severing of actin filaments. It includes (1) acceleration of Pi release from FADPi subunits, (2) severing only when two or more neighboring FAD subunits are bound to cofilin molecules, (3) the cooperative binding phenomenon where cofilin will have higher binding affinity for the FAD subunit which has a neighboring cofilin-bound FAD.

Availability of experimental data from the *in vitro* (test tube) experiments provided a great opportunity to validate the Open Model by running ODE simulations representing a closed well-mixed compartment. Numerous ‘compartmental’ (ODE) models were run for different values of total actin, Cap, cofilin, profilin, and thymosin- $\beta 4$. To mimic the *in vitro* experimental conditions, Arp2/3-mediated nucleation and branching were not included in these ODE simulations. Overall the results reproduced the effects of nucleotide exchange, profilin and thymosin- $\beta 4$ on actin turnover, F-actin concentration, and filament length reported and simulated by ([Bindschadler et al., 2004](#)). Additionally, simulations agreed well with the experimental data on the effect of Cap, fragmentation, and annealing on the average filament length. Overall, the simulations reproduced numerous experimental studies in which each of these system variables had been carefully controlled ([Carlier and Pantaloni, 2007](#); [dos Remedios et al., 2003](#); [Pollard and Borisy, 2003](#); [Pollard and Cooper, 1986](#)) (and see the article by Carlier *et al.* in this work). Running compartmental simulations not only offered an initial model validation, but the final steady state values for these calculations served as appropriate initial conditions (stable starting concentrations) for the spatial simulations with Arp2/3 activation.

One of the key VCell capabilities is to simulate cellular dynamics in space. The ultimate goal of the Open Model was to investigate the process of actin dendritic nucleation in lamellipodial protrusion. For this purpose the Open Model adopted an idealized 3D geometry of a migrating cell with a thin lamellipodium and a larger volume cell body ([Figure 7\(c\)](#)) to run additional virtual experiments. In spatial simulations, biochemical reactions are complemented with diffusion and flow of the molecular species. As a result Virtual Cell generates and solves a system of ‘PDEs’ constrained by mass conservation.

The mechanism of Arp2/3-mediated branch formation is a multiple step process. In the Open Model it was reduced to a single step to achieve computational efficiency and therefore

reduce simulation time for 3D virtual experiments. Arp2/3 activation and side branching was implemented as proposed in the modeling study by (Carlsson *et al.*, 2004). Cytosolic Arp2/3 complex is recruited to the membrane and activated by a membrane-bound NPF (activeNWASP). Activated and membrane-localized Arp2/3 recruits two actin monomers (unbound or bound to profilin) and binds to the side of the preexisting filament. Monomer recruitment and side binding occurs in one step and results in production of a branch and a free barbed end. This is an example of one of the branching reactions:

There are six nucleation reactions because FA can be in three states and GAT can also be in the GAT-Prof (profilin-bound) form.

Diffusion of all the monomeric species and actin-binding proteins was assigned a diffusion coefficient of $D_{\text{GActin}} = 5 \mu\text{m}^2 \text{s}^{-1}$, consistent with experimental data. Long and branched actin filaments diffuse slower than monomers, however. One of the modeling challenges was to incorporate the dependence of F-actin fragment diffusion on the filament length and branching properties of the polymer. The following equation was used to model F-actin diffusion:

$$\frac{D_{\text{GActin}}}{\text{FilamentLength}} \times (1 - \text{BrF})$$

'FilamentLength' is the average length of actin filament. It is calculated by dividing total F-actin (which includes all nucleotide FA forms, FA species with bound cofilin or Arp2/3, and all end species) by the number of filaments, which is calculated as equal to half the number of ends. Diffusion is also reduced (multiplication by $(1 - \text{BrF})$) by the fraction of filaments that are branched.

The rapidly polymerizing branched actin network produces force against the plasma membrane (Figure 5(b)). This results in rearward movement of the F-actin network and also lamellipodial protrusion. The flow of the network is modeled explicitly with an advection (velocity) expression: $v_i = v_i^{\text{max}} \times \text{BrF}$. The flow is proportional to 'BranchFraction' because only actively polymerizing filaments that are connected to the dendritic network are expected to undergo the rearward movement. An experimentally determined value for $v_i^{\text{max}} = 800 \text{ nm min}^{-1}$ (Ponti *et al.*, 2005) was employed.

To simulate actin dynamics at the leading edge of the protruding cell in 3D, the Open Model triggered the dendritic nucleation mechanism by activating NPF (ActiveNWASP) at the membrane at the leading edge (Figure 7(c)). Starting with species concentrations obtained from the steady state of corresponding compartmental simulations, Arp2/3 complex becomes activated by ActiveNWASP and stimulates branching at the front of the cell. In live cells growing branched filaments produces force by the Brownian ratchet mechanism (refer to the Section Conceptual Models of Mechano-chemical Control of Cell Motility and Shape) that pushes the plasma membrane forward. Even though Virtual Cell does not model the moving membrane or force-velocity coupling, it can represent the resulting rearward motion of actin network by a combination of the advection and diffusion, as discussed above. Simulation results quantitatively reproduced F-actin accumulation in the

lamellipodium, velocity fields of the rearward motion of actin network, average filament length, and profilin-bound G-actin concentration (Figure 7(d)). F-actin accumulation is a hallmark of lamellipodial protrusion (Abraham *et al.*, 1999) and it was predicted accurately by the model with a maximum concentration of $725 \mu\text{M}$ at the tip and $120 \mu\text{M}$ (depletion) in the body of the cell; the total actin (GA + FA) in the system was $200 \mu\text{M}$. Due to rapid assembly of branched actin network in a small volume of the lamellipodial tip, profilin-bound G-actin becomes depleted (Figure 7(d)). The simulated average length of the filaments is consistent with electron microscopy measurements (Svitkina and Borisy, 1999). Filaments at the tip are much shorter (40 subunits) than in the body of the cell (400 subunits). The velocity field that characterizes rearward motion of the network also agrees with the experimental observations by speckle microscopy (Ponti *et al.*, 2005).

The Open Model highlighted a few important aspects of cooperative behavior of actin regulatory proteins. The role of cofilin in regulating actin network dynamics has been a subject of debate. It was proposed to promote depolymerization and decrease in F-actin levels (Hotulainen *et al.*, 2005; Kueh *et al.*, 2008) as well as stimulate polymerization and cell protrusion and produce new filaments (Endo *et al.*, 2003; Ghosh *et al.*, 2004; Ichetovkin *et al.*, 2002). The model offers a potential explanation of the conflicting reports. After running multiple simulations with various initial concentrations of cofilin and Cap we noticed that cofilin could either suppress or promote Arp2/3-dependent F-actin accumulation (Figure 7(e)). With low amounts of both cofilin and Cap there are enough barbed ends to produce F-actin. Increasing Cap concentration will result in a lower number of barbed ends and therefore will inhibit F-actin increase. When cofilin concentration is high and Cap is low then F-actin production is also inhibited due to small G-actin pool. Increasing capping concentration will elevate monomer concentration and therefore will result in F-actin accumulation at the tip (Figure 7(e)). These results are consistent with the model by (Carlsson *et al.*, 2004) that predicted requirement of barbed-end capping for F-actin production due to high severing activity.

Investigation of assembly and disassembly rates in the simulated 3D lamellipodium reproduces a complex dynamical behavior of the dendritic actin network. Figure 7(f) reveals a sharp boundary between polymerization and depolymerization located $1 \mu\text{m}$ from the cell edge, where negative rates that indicate disassembly are color coded and positive rates are shown in white (Figure 7(f) top). The sharp assembly-disassembly transition was originally discovered with the speckle microscopy studies (Ponti *et al.*, 2004, 2005). The Open Model successfully reproduces and provides an explanation for this phenomenon. The boundary is positioned right between the regions of maximum barbed (right at the tip) and pointed end concentrations ($\sim 2 \mu\text{m}$ from the edge) (Figure 7(f) bottom). Therefore the assembly-disassembly transition is very sensitive to the debranching since it exposes additional pointed ends that were previously capped by the Arp2/3 complex.

We briefly highlight two additional studies, for which the Open Model served as a starting point. These are examples of how the original model was adapted to different experimental systems and consequently to another geometric and biochemical conditions.

Fluorescent recovery after photobleaching (FRAP) and chromophore-assisted laser inactivation (CALI) microscopy techniques are used extensively to study actin dynamics. In order to interpret the experimental result of FRAP and CALI of enhanced green fluorescent protein (eGFP)-Cap, Kapustina developed a model (Kapustina *et al.*, 2010) where eGFP-Cap could be virtually bleached and remain active (as in FRAP) or become inactive (as in CALI) (Figure 8(a)). The model adapts all the mechanisms from the Open Model with two enhancements: modified Cap-containing reactions, to which fluorescent and nonfluorescent species were added; mechanisms involving vasodilator-stimulated phosphoprotein (VASP) bundling and uncapping activities. The results from simulated FRAP experiments allowed estimates of Cap dissociation rate which was found to be much faster than *in vitro*. CALI simulations of experiments in which Cap activity was locally ablated, produced results that required anticapping activity. Thus, the model suggested that VASP exhibits cooperativity to induce the anticapping effect, consistent with suggestions from *in vitro* VASP biochemistry.

A model of Nck-induced actin comet tails (Ditlev *et al.*, 2012) expands the signaling mechanism that leads to N-WASP activation (Figure 8(b) top). Nck is a adaptor protein that normally is recruited to phosphorylated tyrosines; it recruits a number of actin regulatory molecules including N-WASP. Experimentally increasing the density of Nck molecules at the membrane resulted in a nonlinear response of actin polymerization. The source of the nonlinearity was discovered by testing, 'in silico,' three different stoichiometries of Nck/N-WASP/Arp2/3 interaction and quantitatively comparing simulated and experimental actin comets. Based on this

comparison, the authors proposed a 4:2:1 stoichiometry for Nck/N-WASP/Arp2/3 and a critical role of WIP (WASP interacting protein) in the signaling complex at the membrane. The model predictions were rigorously tested and confirmed using quantitative fluorescent microscopy. For instance the model accurately predicts comet tail length and the number of actin molecules in the comet (Figure 8(b) bottom).

In this section, we first provided a brief overview of the approaches toward detailed models of actin dynamics with a focus on the core mechanisms of actin polymerization and how it is regulated to drive cell motility. The models chosen were just illustrative and not meant by any means to comprehensively review the many contributions to this field. Rather, they were meant to exemplify what might be learned from continuum versus discrete or from compartmental versus spatial models and how these various approaches can be applied to the complexity of actin biochemistry. We then focused on how the Open Model was developed, including some of the key approximations required to confront the combinatorial complexity of polymerization and its regulation; indeed, the development of such approximations, which lump multiple explicit species and reactions into a small set of tractable variables and equations, is the most creative aspect of the modeling process. Finally, we described, using the Open Model, how Virtual Experiments could be deployed to provide fresh insight into several real experimental results and could even be used to guide the design of experiments. We encourage readers of this article to access and use the Open Model by logging onto the Virtual Cell (see Section Relevant Websites) and opening the public model called 'les: Actin Dendritic Nucleation.'

Figure 8 Examples of models based on the Open Model. (a) CALI and FRAP of Caps. Reaction diagram of barbed-end capping mechanism from the model by Kapustina *et al.* (2010). Note 'dark' Cap species in pink rectangles. In FRAP 'dark' Cap is active and able to participate in reactions. For CALI experiments the 'dark' Cap is inactive. VASP can bind each type of free barbed ends and therefore competes with Cap. (b) N-WASP/Arp2/3 signaling in actin comets. (Top) Arp2/3 activation at the membrane as in the model by Ditlev *et al.* (2012). Activation mechanism was modified to include Nck activation of N-WASP, WIP recruitment, and proposed 4:2:1 Nck/N-WASP/Arp2/3 stoichiometry. (Bottom) Simulation result for total F-actin in the actin comet induced by aggregation of Nck SH3 domains. Actin comets move along the membrane being propelled by polymerizing actin. Comet propulsion is modeled through the advection parameter.

Conclusion

We presented the dichotomy between ‘conceptual’ and ‘detailed’ models of actin-dependent cell biology as quite absolute. This has been largely the case in practice, where the two classes of models have been divided both philosophically and with respect to the kinds of questions being asked of them. With regard to the former, conceptual models are primarily concerned with a global picture of the physics underlying a cellular behavior; detailed models care about the role of each molecular player in the cellular orchestra. With regard to differences in research questions, conceptual models have been primarily concerned with the interplay of cell mechanics and polymer physics; detailed models have been concerned with the biochemistry of signaling to and regulation of actin dynamics. We can certainly look forward to the inevitable blending of these modeling approaches. But this will require new physical, mathematical, and computational technologies that can couple cell mechanics, moving boundaries, and complex reaction-diffusion systems. We are beginning to see the emergence of such approaches (Novak and Slepchenko, 2014).

To make this article maximally accessible, we have deliberately avoided the use of mathematical equations. However, mathematical modeling, of course, requires the solution of equations. Indeed, all of the studies we used to exemplify various modeling approaches, did produce their simulations by solving complex mathematical problems. This invariably requires the use of numerical methods and computers. We urge the mathematically inclined reader to go to the primary sources in the bibliography to see how the ideas we presented were translated into equations. Thankfully, there are many readily available software tools to help cell biologists develop mathematical models and run simulations from them (see Section Relevant Websites). We look forward to the time when modeling will be as common a tool for the cell biologist as the microscope or the pipet. Indeed, the most powerful application of modeling is as a tool that is fully integrated within an experimental study.

Introduction

Although one can trace the first metabolic experiments to Santorio Sanctorius (1561–1636) who investigated the balance of food intake and what he called insensible perspiration, actual studies into metabolism didn't start until Eduard Buchner in the late nineteenth century demonstrated fermentation in yeast cell-free extracts. It was hypothesized that the fermentation was carried out by a heat labile cytoplasmic substance which he called 'zymase.' Following this work, progress was rapid (Cornish-Bawden, 1997) with the discovery that glucose fermentation was carried out via a series of distinct reactions, each reaction catalyzed by a specific enzyme. Collectively the sequence of reactions was named glycolysis. The early twentieth century right up to the 1970s was a golden age for research in metabolism and enzymology. All the major metabolic pathways were elucidated together with a considerable amount of information on the mechanisms by which metabolism was regulated.

It has now been roughly 120 years since Buchner created the first fermenting cell-free extract and yet our understanding of metabolism is still incomplete. It is true that through modern genome-scale studies (Palsson, 2007; Terzer *et al.*, 2009; Thiele and Palsson, 2010; Henry *et al.*, 2010; Santos *et al.*, 2011), great numbers of organisms have had their metabolic potential mapped out in considerable detail. However, these maps are static and what is still missing to a large extent is understanding the dynamics and general operating principles of metabolism.

This article will be concerned with some of the operational principles of metabolism (Fell, 1997) and the theoretical principles that allow us to understand such a complex system (Heinrich and Schuster, 1996).

Metabolism

The first cellular networks to be discovered were the metabolic pathways such as Glycolysis in the 1930s and the Calvin cycle in the 1940s. These pathways were elucidated by a combination of enzymatic inhibitors and the use of radioisotopes such as Carbon-14. The Calvin cycle, for example, was discovered by following the fate of carbon when algae were exposed to ^{14}C -labeled CO_2 . With the development of microbial genetics, significant progress was also made in uncovering other pathways by studying mutants and complementing different mutants of a given pathway to determine the order of steps.

The reaction steps in a metabolic pathway are catalyzed by enzymes and we now know there are thousands of enzymes in a given organism catalyzing a great variety of pathways. The collective sum of all reaction pathways in a cell is referred to as metabolism and the small molecules that are interconverted are called metabolites.

Traditionally, metabolism is classified into two groups, anabolic (synthesis) and catabolic (breakdown). Coupling between the two metabolic groups is achieved through cofactors of which a great variety exist although two widely distributed cofactors include the pyridine nucleotides in the form of NAD and NADP and the adenine nucleotides in the form of ATP, ADP, and AMP. These cofactors couple redox and phosphate respectively by forming reactive intermediates that enables catabolism to drive anabolism. A primary catabolic process is cellular respiration where starting molecules such as glucose are oxidized in a stepwise fashion. The energy released is captured in the form of ATP and the oxidized product, water, and carbon dioxide are released as waste. The ATP can be used in turn to drive anabolic processes such as amino acid or lipid biosynthesis. In general, metabolic pathways are regulated at multiple time scales. For example, the rapid response to moment by moment fluctuations in supply and demand of molecular building blocks is most likely achieved through allosteric regulation. In contrast, large-scale remodeling of pathways via genetic regulation is generally slow and in response to significant changes in an organism's environment, for example, changes nutrient supply.

Figure 1 shows a section of the glycolytic pathway which converts glucose to pyruvate with the production of ATP and NADH. The diagram also shows the many negative and positive feedback and feedforward regulatory loops in glycolysis. Not all of these are present in all organisms, however, many are. Note the six regulatory signals that converge on 6-phosphofructose-1-kinase (also known as phosphofructokinase) and fructose biphosphatase (labeled 2 and 3). One of the aims of metabolic research is to quantify regulation and to understand the operational principles of such control. The literature on the dynamics of metabolic pathways is huge and includes many subtle concepts on how these systems operate. Given the size of the field, only a brief overview of the current state of knowledge can be given here. We will not, for example, consider the structural properties of metabolic networks (Clarke, 1980; Reich and Selkov, 1981; Hofmeyr *et al.*, 1986; Reder, 1988; Schuster and Schuster, 1993; Edwards *et al.*, 2002; Sauro and Ingalls, 2004; Palsson, 2007) nor the effect of spatial gradients or compartments. We start with some fundamental concepts, proceed to some general methodologies, and then describe the properties of some common metabolic motifs.

Fundamentals

Stoichiometric Networks

Almost all cellular processes involve some kind of chemical process such as binding, unbinding, or transformations, often in particular stoichiometric amounts. A network of reactions that is governed by mass-balance is termed a stoichiometric network. This is to distinguish the network from other

Figure 1 A section of glycolysis with negative and positive regulation shown. (1) Hexokinase; (2) 6-Phosphofructose-1-kinase; (3) Fructose biphosphatase; (4) Pyruvate kinase; (5) Entry to citric acid cycle; (6) To oxidative respiration.

Figure 2 Simple two-step pathway.

graph-based networks that describe associativity or interactions between components but without any reference to stoichiometry. A key characteristic of stoichiometric networks is mass-balance. Consider a simple network comprising two reactions, v_1 and v_2 , with a common species, S . We will assume that the first reaction, v_1 , produces S and the second reaction, v_2 , consumes S (Figure 2).

According to the law of conservation of mass, any observed change in the amount of species, S , will be due to the difference between the inward rate, v_1 and outward rate, v_2 . That is, the change in concentration of S will be given by the difference in the two rates, leading to the differential equation:

$$\frac{dS}{dt} = v_1 - v_2 \quad [1]$$

Figure 3 Mass-balance: The rate of change in species S_i is equal to the difference between the sum of the inflows and the sum of the outflows.

This equation is called a 'mass-balance equation' and for more complex systems such as the one shown in Figure 3 where there are multiple inflows and outflows, the mass-balance equation is given by:

$$\frac{dS_i}{dt} = \sum \text{Inflows} - \sum \text{Outflows} \quad [2]$$

The study of stoichiometry is a key component to understanding the dynamics of metabolism (Sauro, 2014).

Stoichiometry Matrix

When describing multiple reactions in a network, it is convenient to represent the stoichiometries in a compact form called the 'stoichiometry matrix.' Different disciplines use different symbols for the stoichiometry matrix. For example, the chemistry community has traditionally used ν (Aris, 1965), the constraint-based approach community (Palsson, 2007), S and the biochemical systems community, N . In this book the symbol ' N ' will be used to avoid any confusion when using ' S ' to represent a species.

The stoichiometry matrix (Stephanopoulos *et al.*, 1998; Sauro, 2014) is a m row by n column matrix where m is the number of species and n the number of reactions:

$$N = m \times n \text{ matrix}$$

The columns of the stoichiometry matrix correspond to the individual chemical reactions in the network, the rows to the molecular species, one row per species. Thus the intersection of a row and column in the matrix indicates whether a certain species takes part in a particular reaction or not, and according to the sign of the element, whether there is a net loss or gain of substance, and by the magnitude, the relative quantity of substance that takes part in that reaction. In general the stoichiometry matrix has the form:

$$N = \begin{matrix} & \leftarrow v_j \rightarrow \\ \begin{matrix} \uparrow \\ S_i \\ \downarrow \end{matrix} & \begin{bmatrix} c_{ij} & \cdots & \cdots \\ \vdots & & \\ \vdots & & \end{bmatrix} \end{matrix}$$

where c_{ij} is the stoichiometry coefficient for the i th species and j th reaction. The stoichiometry matrix for the simple chain of reactions which has five molecular species and four reactions is shown below. The four reactions are labeled v_1 to v_4 .

The stoichiometry matrix for this simple system is given by:

$$N = \begin{array}{cccc|c} & v_1 & v_2 & v_3 & v_4 & \\ \hline & -1 & 0 & 0 & 0 & S_1 \\ & 1 & -1 & 0 & 0 & S_2 \\ & 0 & 1 & -1 & 0 & S_3 \\ & 0 & 0 & 1 & -1 & S_4 \\ & 0 & 0 & 0 & 1 & S_5 \end{array}$$

The rows and columns of the matrix have been labeled for convenience. Normally the labels are absent.

Reaction Rates

The stoichiometry matrix has no information concerning the rate of reaction, that is, how the rate of transformation is a function of the reactant and product species. Rates of reaction, often denoted by the symbol v , is measured with respect to a given molecular species normalized by the species' stoichiometric coefficient. This ensures that no matter which molecular species in a reaction is measured, the reaction rate is uniquely defined for that reaction. The kinetic rate laws that govern the rate of reaction are extremely varied, ranging from simple mass-action kinetic laws to complex allosteric and cooperative mechanisms. A discussion of these kinetic rate laws is beyond the scope of this article but readers can consult the texts by Sauro (2012) and Cornish-Bowden (2012). For a given pathway, the set of all reaction rates is conveniently represented by the reaction rate vector, v .

Dynamics

The time evolution of a metabolic pathway can be described using a set of differential equations. Equation [1] illustrates a single differential equation that describes the rate of change of a single metabolite S . In larger systems there will be as many differential equations as there are metabolites in the pathway. A compact way of depicting such a system is given by the equation:

$$\frac{ds}{dt} = Nv \quad [3]$$

where N is the stoichiometry matrix and v the vector of reaction rates. This system of equations can be solved numerically (Sauro, 2014) to produce the time evolution for all the metabolites in the pathway. Usually such systems evolve to a steady state where the metabolite levels are unchanging but the pathway sustains a finite flux from the pathway's source to its sink. At steady state the system equation has the form:

$$0 = Nv \quad [4]$$

Implicit in these equations are two assumptions. The first is that we are dealing with large numbers of molecules. This enables us to describe concentration changes using continuous variables. If molecule numbers fall into the 100 particle range, it is often recommended to model systems using a stochastic discrete approach (Gillespie, 2007). The second assumption we make is that we assume that the compartment in which the reactions take place is well mixed. This means there are no concentration gradients, that is, diffusion is faster than the enzymatic processes. Although these assumptions may seem restrictive it is nevertheless remarkable that many metabolic systems can be effectively modeled under these assumptions (Chassagnole *et al.*, 2001; van Eunen *et al.*, 2012; Smallbone *et al.*, 2013).

Almost all dynamical studies of metabolic pathways revolve around the study of eqns [3] and [4].

Enzyme Response

Since enzymes are the functional units of metabolism, it is important to understand how an enzyme responds to changes in its environment. A measure that describes this response is called the elasticity coefficient (Kacser and Burns, 1973; Sauro, 2012). Elasticities describe how sensitive a reaction rate is to changes in reactant, product, and effector concentrations. They represent the degree to which changes are transmitted from the

Figure 4 (a) The slope of the reaction rate versus the reactant concentration scaled by both the reactant concentration and reaction rate yields the elasticity, ϵ_S^v . (b) If the log of the reaction rate and log of the reactant concentration are plotted, the elasticity can be read directly from the slope of the curve. Curves are generated by assuming $v = S/(2 + S)$.

Figure 5 Simple branched pathway. This pathway has three different fluxes, J_1 , J_2 , and J_3 which at steady state are constrained by $J_1 = J_2 + J_3$.

immediate environment to the reaction rate (Figures 4 and 5). From a systems perspective they are critical components in understanding how a disturbance, such as the introduction of a drug applied at one or more points in a cellular pathway, propagates to the rest of the system. It is the magnitude and signs of the elasticities that determines how far and at what strength the disturbance travels. Elasticities are therefore central in helping us understand how networks and metabolism in particular functions.

Elasticity Coefficients

The elasticity coefficient is defined by the following expression:

$$\varepsilon_{S_i}^v = \left(\frac{\partial v}{\partial S_i} \frac{S_i}{v} \right)_{S_j, S_k, \dots} = \frac{\partial \ln v}{\partial \ln S_i} \approx v/S_i \quad [5]$$

Operational Definition

The elasticity is the fractional change in reaction rate in response to a fractional change in a given reactant or product while keeping all other reactants and products constant.

Since the elasticity is expressed in terms of fractional changes, it is also possible to get an approximate value for the elasticity by considering percentage changes. For example, if we increase the substrate concentration of a particular reaction by 2% and the reaction rate increases by 1.5%, then the elasticity is given by $1.5/2 = 0.75$. The elasticity is however only strictly defined (see eqn [5]) for infinitesimal changes and not finite percentage changes. As long as the changes are small, the finite approximation is a good estimate for the true elasticity.

Pathway Responses

The response of a pathway to a perturbation can be described in two ways: (1) large-scale transients and remodeling of pathways that occur as a result of major changes to an organism state, for example, as a result of changes to nutrient supplies; (2) changes as a result of the moment by moment adjustments of a pathway due to small perturbations in the milieu of the organism. Unfortunately, there is little or no theory that allows us to understand large-scale transients, this is an area of active research and recent experimental results suggests there is a rich vein of untapped biology awaiting to be discovered (Zampar *et al.*, 2013; Klumpp and Hwa, 2014). Here we will focus on how pathways respond to moment by moment perturbations, this is a much more developed area of research and has revealed considerable insight into the dynamical operation of pathways.

The vocabulary used to describe metabolic regulation has on the whole not been well defined. Thus terms such as control and regulation are used in many different places with different meanings. In the vernacular, the word control usually means the ability to influence, command, or to restrain a situation or process (In engineering, control theory refers to the body of knowledge concerned with the design and study of systems that can perform specific tasks or achieve a particular objective.). Here the term control will be used, as set forth by Kacser and Burns (1973) to describe how much influence a given reaction step in a network has on the system. To make matters simpler we will consider the system to be at steady state so that control will refer to how much influence a given reaction step has on the steady state, that is how steady state fluxes and concentrations are influenced. General reviews on 'metabolic control analysis' can be found in the following sources (Fell, 1997; Qian and Beard, 2006). Non-steady state analysis is still not fully developed but readers can consult papers by Acerenza *et al.* (1989), Heinrich and Reder (1991), Reijenga *et al.* (2002), Ingalls and Sauro (2003), and more general information in the textbook by Heinrich and Schuster (1996).

Most reaction steps in a cell are controlled by proteins and the question then becomes how much influence a given protein has on the system's steady state. Experimentally such control can be measured by changing the concentration of an enzyme or changing its activity via an inhibitor and measuring the effect on the steady state flux and species concentrations. Concentrations of proteins can be changed in various ways, for example, by using irreversible inhibitors, changing the promoter consensus sequence on the gene that codes for the protein or by employing antisense RNA to reduce the expression level.

Control: The degree of control that a particular reaction step has on a flux or species concentration is called the 'control coefficient.'

In addition to investigating how individual reaction steps control the fluxes and concentrations in a network, we are also interested in how external factors influence the network. Examples of external factors include the level of nutrients, hormones, and of particular interest to human health, therapeutic drugs. In these situations, rather than use the word control, we will use the term response. Thus a biological cell will have a response to a particular infusion of a drug. The degree of influence an external factor has on a biological system is described using 'response coefficients' (Kacser and Burns, 1973).

Finally, the degree to which an external factor or an enzyme has on a cellular network will depend on the network's regulatory mechanisms. The degree of regulation at a given reaction step is described using the 'regulatory coefficient' (Sauro, 1990; Hofmeyr and Cornish-Bowden, 1991; Brand, 1997; Brand and Curtis, 2002).

Control Coefficients

Control coefficients are used to describe how much influence (i.e., control) a given reaction step has on the steady state flux or species concentration level. It is common to measure this influence by changing the concentration of the enzyme that

catalyzes the reaction. We define the control coefficients as follows:

$$C_{E_i}^J = \frac{dJ}{dE_i} \frac{E_i}{J} = \frac{d \ln J}{d \ln E_i} \approx J/E_i \quad [6]$$

$$C_{E_i}^{S_j} = \frac{dS_j}{dE_i} \frac{E_i}{S_j} = \frac{d \ln S_j}{d \ln E_i} \approx S_j/E_i \quad [7]$$

The flux control coefficient measures the fractional change in flux brought about by a given fractional change in enzyme concentration and the concentration control coefficients measure the fractional change in species concentration given a fractional change in enzyme concentration.

For example, we could increase the copy number of a given gene to change the concentration of the expressed protein and find out how much influence the gene has on its own gene product and on other processes. It is important to note however, that knowing the values of the control coefficients does not tell us why certain enzymes or proteins have more influence than others. To answer the 'why' question we must examine what determines the relationship between control coefficients and how they are related to the elasticities of the network. The first set of relationships are called the summation theorems (Kacser and Burns, 1973; Ingalls, 2013):

$$\sum_{i=1}^n C_{E_i}^J = 1 \quad \sum_{i=1}^n C_{E_i}^{S_j} = 0 \quad [8]$$

These relationships imply the following assertions about control in a pathway:

1. Control is shared throughout a pathway, that is the degree to which flux is limited in a pathway is shared. It is unlikely that only a single step in a pathway limits flux.
2. If one step gains control, one or more other steps must loose control.
3. Control coefficients are system properties, they can only be computed or measured in the intact system. Inspection of a single enzymatic step will not reveal its degree of control (or influence) on the pathway.

Rate-Limiting Steps

In much of the literature and many contemporary textbooks, one will often find a brief discussion of an idea called the rate-limiting step. In textbooks we will find statements such as:

In order to exert control on the flux of metabolites through a metabolic pathway, it is necessary to regulate its rate-limiting step. (Voet and Voet, 2004, p. 522)

These statements are not consistent with the idea that control is shared among all steps. Other than a few books such as the 4th edition of Lehninger Biochemistry, most textbooks will have similarly expressed statements. A common argument is that a metabolic pathway will contain a single step that has overall influence over the pathways' flux. This concept drives much of metabolic engineering and drug targeting of metabolism. What is most surprising however is that a simple quantitative analysis shows that it cannot be true, and there is ample experimental evidence (Heinisch, 1986; Burrell *et al.*, 1994) to support the notion of shared control.

The concept of the rate-limiting step is both inconsistent with logic and more importantly experimental evidence.

The confusion over the existence of rate-limiting steps stems from a failure to realize that rates in cellular networks are governed by the law of mass-action, that is, if a concentration changes, then so does its rate of reaction. Analogies that are sometimes used such as traffic flow or supermarket checkout do not apply because in both cases flow is not governed by either the number of cars or customers waiting. In terms of control coefficients, a rate-limiting step can be interpreted as a flux control coefficient of unity. This means, by the summation theorem, that all other steps (at least in a linear chain) must have flux control coefficients of zero. However, when we consider branched and cyclic systems it is possible to have flux control coefficient much greater than one (other control coefficients must then be negative to satisfy the summation theorem). In these cases what adjective should we use, hyper-rate-limiting steps? In the final analysis, it is better to assign a value to the rate limitingness of a particular step.

For example, a rate-limiting step in glycolysis is often considered to be phosphofructokinase since it is regulated by many effectors. Such an assertion makes perfect sense if metabolism is seen as a series of connected pipes and tanks with valves that can be used to independently turn on and off the flow of water. However, metabolism is not like this, the valves are part of the system. This makes an understanding of how pathways are controlled much more subtle (Morandini, 2009). Measurements (Heinisch, 1986; Ruijter *et al.*, 1997) have shown, for example, that phosphofructokinase is in fact not rate limiting even though it is heavily regulated.

Connectivity Theorems

In the previous section, we saw that there are summation theorems relating the control coefficients. Here we will introduce an additional set of theorems that relate the control coefficients to the substrate, product, and effector elasticities. These theorems are called the 'connectivity theorems' and represent the most important result in metabolic control analysis (Kacser and Burns, 1973; Wanders *et al.*, 1984; Westerhoff *et al.*, 1984; Kholodenko *et al.*, 1994; Ingalls, 2013). The theorem relates the control coefficients to the elasticities, that is, they relate system-wide properties to local properties. They help us explain why some enzymes have the degree of influence they have.

For a species, S , that interacts with r other steps, the connectivity theorems are written as:

Flux Connectivity Theorem with respect to a common metabolite, S_k where r is the number of interactions it makes with neighboring reaction steps.

$$\sum_{i=1}^r C_{E_i}^J \epsilon_{S_k}^{v_i} = 0 \quad [9]$$

Concentration Connectivity Theorem with respect to the common metabolite, S_k , where r is the number of interactions it makes with neighboring reaction steps.

$$\sum_{i=1}^r C_{E_i}^{S_k} \epsilon_{S_k}^{v_i} = -1 \quad [10]$$

Concentration Connectivity Theorem with respect to the common metabolite, S_k , and a distant metabolite, S_m , where r is the number of interactions it makes with neighboring reaction steps.

$$\sum_{i=1}^r C_{E_i}^{S_m} \epsilon_{S_k}^{E_i} = 0$$

By combining the connectivity theorems with the summation theorems we can get a complete picture of how small perturbations propagate through a system (Fell and Sauro, 1985).

Metabolic Motifs

There are a number of common pathway motifs found in metabolism. Here we will describe the dynamical properties of some of the more common ones by analyzing the effects of small perturbations on the system. For a detail discussion, including proofs, the reader should consult the textbook by Heinrich and Schuster (1996).

Linear Pathways

Linear pathways, that is a sequence of consecutive reactions, are surprisingly uncommon in metabolism. Most of the metabolism is either heavily branched or coupled to other processes via cofactors such as ATP and NADH. Although pure linear pathways are rare, their study provides a background to gauging other more complex motifs (Kacser, 1983; Heinrich and Rapoport, 1974; Savageau, 1976). Consider the linear pathway:

which has m floating species and n reactions ($n=m+1$). X_0 and X_1 are fixed species representing the source and sink pools respectively. If we assume reversible mass-action kinetics for each of the reactions it is possible to show that the control coefficients are less than one but greater than zero, $0 \leq C_i^j \leq 1$.

If we assume that each equilibrium constant is greater than one and equal to each other it is possible to show that two adjacent steps, for example the i th and $i+1$ th step, are related by $C_i^j > C_{i+1}^j$, that is 'earlier steps' will have more flux control. This pattern applies across the entire pathway such that steps near the beginning of a pathway will have more control than steps near the end. We will call this effect 'front loading' and gives some credence to the traditional idea that the first or committed step is the most important step in a pathway. However, front loading only applies to unregulated pathways, the moment we add regulation to the pathway this picture changes.

Another general result to come from an analysis of linear pathways is steps close to equilibrium tend to have less flux control. This result that has been known for sometime, even before the advent of a systematic analysis. However, what a more systematic analysis shows is that it is the context within which the near equilibrium reaction resides that is important in determining its flux control coefficient (Fell and Sauro, 1986). This means that identifying a step that is close to equilibrium is not a sufficient criterion for asserting it has a low flux control.

Irreversibility: In a linear pathway governed by 'linear kinetics' and without the presence of regulatory interactions, all steps downstream of an irreversible step, ($\rho_i=0$), have no flux control.

Branched Pathways

Branching structures are probably one of the most common patterns in biochemical networks. Even a pathway such as glycolysis, often depicted as a straight chain in textbooks is in fact a highly branched pathway.

At any given branch node, where a node is a molecular species, there will be conservation of mass. Given a node species, x_i , with b branches entering the node and d branches leaving, the net rate of change in concentration of x_i is:

$$\sum_{i=1}^b v_i - \sum_{j=1}^d v_j = \frac{dx_i}{dt}$$

At steady state when $dx_i/dt=0$, it must also be true that:

$$\sum_{i=1}^b v_i = \sum_{j=1}^d v_j$$

In this section we will describe the control of flux through a branched system in response to changes in enzyme activity. Let us consider the simple branched pathway depicted in Figure 5.

In the figure, J_1 , J_2 and J_3 are the steady state fluxes. By the law of conservation of mass, at steady state, the fluxes in each limb will be governed by the relationship:

$$J_1 = J_2 + J_3$$

Given three different fluxes and one intermediate, there will be four sets of control coefficients, one set concerned with changes in the intermediate, S , and three sets corresponding to each of the three fluxes (Kacser, 1983; LaPorte *et al.*, 1984; Fell and Sauro, 1985).

The key observation in branched pathways is the possibility to encounter flux control coefficients in excess of one, that is a 'super rate-limiting' step (Zhang *et al.*, 2013). The effect occurs when a large flux influences a smaller one. Figure 6 illustrates two extremes. The pathway on the right panel (b) shows two large fluxes, J_1 and J_2 having a major impact on the small flux, J_3 . A note to engineers, the sensitivity of the J_2 flux with respect to itself in panel (b) is roughly one. Even more important is that the concentration control coefficient of the intermediate, S , with respect to step 2 is close to zero. In this situation, increasing the flux through J_2 by overexpressing the enzymes along step 2 will lead to proportional flux increases without significantly affecting the flux through J_1 and J_3 .

Futile Cycles

Closely related to branched systems are cyclic pathways. A typical cyclic pathway is shown in Figure 7. For cycling to occur both forward and back reactions must operate. It is typical to find that the forward and reverse reactions are chemically distinct. Often one reaction will be driven by ATP while the other by the hydrolysis of phosphate groups. Typical examples in metabolism include the cycle between glucose

Figure 6 The figure shows two flux extremes relative to the flux through branch J_2 . In case (a), where most of the flux goes through J_2 , the branch reverts functionally to a simple linear sequence of reactions made from J_1 and J_2 . In case (b), where most of the flux goes through J_3 , the flux through J_2 now becomes very sensitive to changes in activity at J_1 and J_3 . Given the right kinetic settings, the flux control coefficients can become very large with values greater than one or less than minus one for activity changes at J_3 . The values next to each reaction indicate the flux control coefficient for the flux through J_2 with respect to activity at the reaction.

Figure 7 Cyclic pathway.

and glucose-6-phosphate and the cycling between fructose-6-phosphate and fructose 1,6-bisphosphate. Such cycles have often been called futile cycles (or better substrate cycles) because of the expenditure of free energy (as ATP) without any apparent benefit. A number of suggestions have been put forward to rationalize this apparent waste of energy. These include heat production, control of flux direction, metabolite buffering, and more sensitive control of the net flux through the pathway. We will only consider the latter here. **Figure 7** shows a typical cyclic pathway embedded in a linear chain. Of interest is the sensitivity of the pathway flux, v_1 or v_4 to changes in v_2 . The simplest assumption to make is that when we change v_2 there is no change in back flux, v_3 . This could be for a number of reasons, for example, v_3 is saturated by its substrate S_2 .

Figure 8 illustrates two situations, a reference state in panel (a) and a perturbation of 5% to v_2 shown in panel (b). Assuming that the entire flux changes appear in output flux v_4 and that v_3 is not changed, then the percentage change in v_4 (or v_1) is 100%, a 20-fold amplification.

This effect can be easily quantified as follows. First we note the flux constraint due to the cycle is:

$$v_1 = v_2 - v_3$$

We then assume that a perturbation in v_2 leads to the same change in v_1 , that is:

$$\delta v_2 = \delta v_1$$

We can now compute the fractional changes in v_1 and v_2 as:

$$\frac{\delta v_1}{v_1} = \frac{\delta v_2}{v_2} \frac{v_2}{v_1}$$

Figure 8 Amplification in a substrate cycle. (a) Reference state, values refer to fluxes at various points, note that $v_1 = v_2 - v_3$. (b) Activation of v_2 by 5% leads to a 100% change in v_1 and v_4 . It assumes that v_3 is not activated by any changes in S_2 .

The degree of amplification is then given by

$$\frac{\delta v_1 / v_1}{\delta v_2 / v_2} = \frac{v_2}{v_1}$$

Since $v_2 = v_1 + v_3$ then

$$\frac{\delta v_1 / v_1}{\delta v_2 / v_2} = \frac{v_1 + v_3}{v_1} = 1 + \frac{v_3}{v_1} \quad [12]$$

This result shows that the higher the cycling rate (v_3) compared to the through flux, the greater the amplification. This equation gives us the maximum degree of amplification possible. In practice, v_3 will not remain unchanged because S_2 rises. In addition, S_1 will fall due to high consumption which will reduce v_2 but increase v_1 due to lower product inhibition. The resulting amplification is therefore a more complicated function than the one suggested by eqn [12]. However, eqn [12] gives the maximum possible amplification.

Negative Feedback

Feedback is widespread in biochemical networks and physiological systems in general. Some form of feedback permeates almost every known biological process. Metabolism is no exception where negative feedback loops can be virtually found in all pathways. Given the ubiquity, negative feedback must serve an important function. On the face of it, feedback is a simple process that involves sending a portion of the output to the input. If the portion sent back reduces the input then the feedback is called negative feedback otherwise it is called positive feedback.

The central mechanism in a feedback circuit is the generation of the error signal, that is the difference between the desired output (set point) and the actual output. The error is fed into a controller (often something that simply amplifies the error) which is used to increase or decrease the process. For example, if a disturbance on the process block reduces the output, then the feedback operates by generating a positive error, this in turn increases the process and restores the original drop in the output.

The figure of the generic negative feedback circuit (Figure 9) is highly stylized which makes it difficult to identify the various components in a real biological system. In addition, biological systems are invariably more complex with multiple nested feedback loops and multiple inputs and outputs. If it is remarkable then even after 50 or 60 years of research, the role of many of the feedback systems in biochemical networks is still highly speculative.

It was Umbarger (1956) and Yates and Pardee (1956) who discovered feedback inhibition in the isoleucine biosynthesis pathway and the inhibition of aspartate transcarbamylase in *Escherichia coli*. It was not long afterwards that some researchers began to investigate such feedback systems mathematically. Probably the most extensive mathematical analysis of biochemical feedback was conducted by Savageau (1972, 1974, 1976), Burns (1971), Kacser and Burns (1973), Othmer (1976), Tyson and Othmer (1978) in the 1970s, and Dibrov *et al.* (1982) in the early 1980s. More recently, Cinquin and Demongeot (2002) have published an interesting review on the roles of feedback in biological systems.

The first question is how can we map the generic diagram (Figure 9) onto a biochemical feedback circuit (Figure 10), on the surface they look similar but the initial impression is misleading.

In order to be clear we need to identify the input (set point), output, the feedback loop, and the process block in the biochemical network (Figure 11).

In naturally evolved systems it is sometimes difficult to identify the various parts in a negative feedback circuit. The output in the block diagram corresponds to the concentration of S_3 . The negative feedback component corresponds to the interaction of S_3 with the allosteric enzyme in the first step. The set point is more problematic but it is most likely embedded in the kinetic characteristics of the allosteric enzyme. Finally, the controller is represented by the steps v_1 , v_2 , and v_3 . The load on the system is represented by the last step, v_4 and other disturbances can be assigned to v_1 , v_2 , v_4 and the input concentration, X_0 .

Graphical Understanding of Feedback

It is possible to appreciate the effect of negative feedback using a graphical approach. Figure 12 shows two plots, one with strong and the other with weak feedback. The plots show the reaction rates v_1 and v_2 as a function of the intermediate species, S , for a simple two-step pathway where S can negatively feedback on to the first step. We assume that the second step follows first-order kinetics so that the v_2 is a straight line. The feedback response curve shows a decline from high to low as S increases. For strong feedback, the decline is steep (left plot). If we now change the rate constant for the second step, this changes the slope of v_2 , this is equivalent to a perturbation in the system. In the case of weak feedback, changes in v_2 result in significant changes to S , this is because the feedback response is shallow. In contrast, when we have strong feedback (left panel), where the slope is very steep, any changes in v_2 results in only small changes in S . In this way we can see how strong negative feedback can buffer changes in v_2 .

Figure 10 Simple four-step pathway with negative feedback.

Figure 11 Simple four-step pathway with negative feedback.

Figure 9 Generic structure of a negative feedback system.

Figure 12 Plot of v_1 and v_2 versus the concentration of S for a simple two-step pathway with negative feedback. Two perturbations in k_2 that determines v_2 are shown. In the left panel where the feedback is strong, changes in k_2 have hardly any effect on S . On the right panel, the same change in k_2 results in a much larger change in S . This illustrates the homeostatic property of negative feedback. Left panel: $v_1 = 1/(1 + S^4)$, Right panel: $v_1 = 1/(1 + S)$.

Control Analysis

We can derive the flux and concentration control coefficients in terms of the elasticities (Sauro, 2009). Note the presence of the feedback term: e_2^1 in the matrix.

With feedback	Without feedback
$C_{E_1}^J = \frac{e_1^2 e_2^3}{e_1^2 e_2^3 - e_1^1 e_2^3 + e_1^1 e_2^2 - e_1^2 e_2^1}$	$C_{E_1}^J = \frac{e_1^2 e_2^3}{e_1^2 e_2^3 - e_1^1 e_2^3 + e_1^1 e_2^2}$
$C_{E_2}^J = \frac{-e_1^1 e_2^3}{e_1^2 e_2^3 - e_1^1 e_2^3 + e_1^1 e_2^2 - e_1^2 e_2^1}$	$C_{E_2}^J = \frac{-e_1^1 e_2^3}{e_1^2 e_2^3 - e_1^1 e_2^3 + e_1^1 e_2^2}$
$C_{E_3}^J = \frac{e_1^1 e_2^2 - e_1^2 e_2^1}{e_1^2 e_2^3 - e_1^1 e_2^3 + e_1^1 e_2^2 - e_1^2 e_2^1}$	$C_{E_3}^J = \frac{e_1^1 e_2^2}{e_1^2 e_2^3 - e_1^1 e_2^3 + e_1^1 e_2^2}$

We can see that the addition of feedback adds a new term to the denominator and to the numerator for $C_{E_3}^J$. If we make the feedback elasticity, e_2^1 , larger we can see that the demand flux control coefficient tends to unity. That is, all control moves out of the feedback loop. In terms of the steam engine analogy, it is equivalent to being able to change the demand on the steam engine without loss of power. This can be seen more clearly if we look at the concentration control coefficients.

$$C_{E_3}^J \rightarrow 1$$

$$C_{E_3}^{S_2} \rightarrow 0$$

In the list below we give the three control coefficients with respect to S_2 . Looking at $C_{E_3}^{S_2}$ we see that as the feedback strength is increased (e_2^1) in magnitude, the control coefficient tends to zero. This means that the feedback locks the concentration of S_2 into a very narrow range in response to changes in demand.

$$C_{E_1}^{S_2} = \frac{e_1^2}{e_1^2 e_2^3 - e_1^1 e_2^3 + e_1^1 e_2^2 - e_1^2 e_2^1}$$

$$C_{E_2}^{S_2} = \frac{e_1^1}{e_1^2 e_2^3 - e_1^1 e_2^3 + e_1^1 e_2^2 - e_1^2 e_2^1}$$

$$C_{E_3}^{S_2} = \frac{e_1^1 - e_1^2}{e_1^2 e_2^3 - e_1^1 e_2^3 + e_1^1 e_2^2 - e_1^2 e_2^1}$$

Classically, allosteric enzymes have been considered as flux controllers. The analysis here suggests the opposite picture. Allosteric enzymes, when part of a negative feedback loop are very poor controllers of flux. Instead allow distal steps to be good controllers of a pathway flux. For demand-driven systems this is a logical arrangement.

The nagging suspicion remain however that intuitively we feel that the regulated step must have some kind of ability to enable the system to operate in the way it does. There are at least two answers to this. The first is that the feedback elasticity will be strongly negative. For example, if the regulated step were determined by a modified Hill-like equation such as:

$$v = \frac{V_{\max} X_o}{S^n + X_o + K_m}$$

where S is the feedback signal, then the elasticity of the reaction rate with respect to the signal is given by:

$$e_S^v = \frac{n X_o K_m}{K_m + (S/K_m)^n}$$

We see that at low signal, S , the elasticity is proportional to n , the Hill coefficient. The reaction is therefore very sensitive to changes in the signal molecule.

The second way to answer the question is to consider the pathway with and without the negative feedback loop. We can compare for example the flux control coefficient on the first step with and without negative feedback. When we remove the negative feedback, the pathway will change to a new state where the concentrations of S_1 and S_2 are higher. To make the comparison fair we should adjust the level of enzyme in the first step to restore the levels of S_1 and S_2 to the values they had before the feedback was removed. When we do this we will also automatically restore the pathway flux to its original value. In practice this means that all the elasticities except for the feedback elasticity are exactly the same in both systems. To keep the analysis simple, let us assume that the product inhibition elasticities, e_1^1 and e_2^2 are both zero. We now take the ratio of the flux control coefficient on the first step, $C_{E_1}^J$, without feedback to the same coefficient with feedback, which will be

denoted by ${}^nC_1^I$:

$$\frac{C_1^I}{{}^nC_1^I} = \frac{\varepsilon_1^2 \varepsilon_2^3 - \varepsilon_2^1 \varepsilon_1^2}{\varepsilon_1^2 \varepsilon_2^3} = 1 - \frac{\varepsilon_2^1 \varepsilon_1^2}{\varepsilon_1^2 \varepsilon_2^3} = 1 - \frac{\varepsilon_2^1}{\varepsilon_2^3}$$

Given that ε_2^1 is negative, the term $-\varepsilon_2^1/\varepsilon_2^3$ is positive. That is:

$$C_1^I > {}^nC_1^I$$

This tells us that for a negative feedback loop to be effective, the flux control coefficient in the unregulated pathway must be higher than the flux control coefficient with feedback. In a sense the first step in the pathway must have some degree of rate limitingness if a negative feedback is to be effective.

Robustness and Supply/Demand

One way to look at metabolic systems is to divide them into two separate but connected blocks, the supply and demand block (Hofmeyr and Cornish-Bowden, 2000; Rohwer and Hofmeyr, 2008; Hofmeyr and Rohwer, 2011). Negative feedback makes this division very straightforward. Consider a factory that makes cars. Should the rate of car production be controlled by the demand or the supply of cars? Economically the most efficient strategy is to let demand decide how many cars to make, this ensure that excess cars do not build up and thereby waste resources. In certain metabolism situations the same reasoning can be used. For example, the production of amino acids would best be determined by the demand from protein synthesis. This means that if protein synthesis slows, amino acid production should also slow. A metabolic system that supplies amino acids should be able to supply amino acids effectively at both high and low demand. One way to do this is to maintain the amino acid level at a relatively constant level independent of the demand block. Let us assume for the moment that there is no feedback regulation in the supply/demand pathway (Figure 13). If demand rises, this will result in the intermediate metabolite, P , falling. As P falls, the ability to supply the increased demand becomes more and more difficult. If demand falls, the flux through the pathway will fall. This will cause the intermediate metabolite, P , to rise. Since the equilibrium constant across the supply block is likely to be large, the concentration of P could raise to toxic high levels as the supply block approach equilibrium at low fluxes.

The solution to avoid both problems at high and low demand is to use negative feedback (Figure 14). With negative feedback, high demand will result in a decrease in the intermediate metabolite, P , which in turn will release repression in the supply block to restore some loss in P . Alternatively, at low

Figure 13 A system divided into supply and demand blocks.

Figure 14 A system divided into supply and demand blocks with negative feedback.

demand, the increase in P will suppress its own production preventing excessive production of P .

Instability

Although negative feedback offers considerable advantages to a system, too much feedback and delays can result in instability in the form of sustained oscillations. There are a number of examples of metabolic systems or metabolism systems interacting with protein networks where negative feedback appears to cause instability and the emergence of sustained oscillations (Richard *et al.*, 1996; Fung *et al.*, 2005; Stricker *et al.*, 2008).

Conclusion

Although the metabolic parts list is almost complete, our understanding of how metabolism operates is still somewhat primitive. Not only is our understanding of the role of the many feedback and feedforward loops incomplete we do not have a clear understanding of the overall economic decisions that cells make to use and allocate metabolic resources. However, recent ground-breaking and exciting work by the Hwa group has started to collect data and models that suggests the beginnings of an economic model of cellular growth (You *et al.*, 2013; Klumpp *et al.*, 2013; Klumpp and Hwa, 2014). In this work, ribosome synthesis and availability takes a central role in determining metabolic dynamics. In this article only a brief and limited review of some of the essential concepts in understanding metabolic dynamics has been given. Important topics such as long-term regulation (Zampar *et al.*, 2013) and metabolic channeling have not been discussed (Srere and Ovadi, 1990; Sauro and Kacser, 1990; Welch and Easterby, 1994; Huang *et al.*, 2001; Dueber *et al.*, 2009; Castellana *et al.*, 2014).

Dynamics of Microtubule Self-Assembly

BT Castle and DJ Odde, University of Minnesota, Minneapolis, MN, USA

© 2016 Elsevier Inc. All rights reserved.

Glossary

Catastrophe The sudden switch from growth to rapid shortening at the microtubule end corresponding to the loss of the guanosine-5'-triphosphate (GTP) cap.

Dynamic instability Microtubule self-assembly process characterized by the stochastic switching between extended phases of growth and rapid shortening.

E-site Exchangeable nucleotide-binding site on β -tubulin.

GTP cap A stabilizing region of tubulin subunits at the plus-end that are bound with GTP at the E-site.

Kinetic stabilization The attenuation of microtubule self-assembly dynamics by microtubule-targeting agents.

N-site Non-exchangeable nucleotide-binding site on α -tubulin.

Plus-end The dynamic end of the microtubule where β -tubulin is exposed.

Rescue Recovery of the growth phase after rapid shortening.

Tip taper The gradual loss of protofilaments at the tip of microtubules.

Cellular Functions of Microtubules

Microtubules are rigid, tubular polymers that constitute one of the three self-assembled filament structures of the cytoskeleton, the other two being filamentous actin and intermediate filaments. Microtubules serve a multitude of functions in cellular processes, a few of which are outlined in [Figure 1](#), and in general serve to support and maintain intracellular organization. One particularly important function of microtubules is to serve as intracellular 'superhighways' for molecular motor-based transport. Molecular motors, such as kinesin and dynein, deliver vesicle-bound cargos to remote locations using ATP hydrolysis as the energy source in the cell, thereby overcoming fundamental diffusional limits. An especially important cargo is the kinetochore, a protein complex that mechanically links the ends of microtubules to chromosomes during mitosis. By tracking the dynamic growing and shortening ends of microtubules, kinetochores use polymerization and depolymerization forces to position chromosomes in the center of the mitotic spindle during metaphase in preparation for chromosome segregation during anaphase. The dynamic organizational support provided by microtubules is particularly important for neurons to form extensive connections via axons and dendrites, which can be up to a meter in length. Transport of intracellular proteins along these axonal and dendritic extensions then exploits microtubule-based molecular motors to deliver cargo throughout the cell. Further, the rigidity of microtubules allows them to generally withstand the pushing and pulling forces necessary to exert their influence over micrometer-scale distances. In general, each of these cellular functions relies on both the microtubule structure and the dynamics of microtubule self-assembly.

Microtubule Structure

Microtubules are composed of globular protein subunits or building blocks, which are heterodimers of α - and β -tubulin. Heterodimeric subunits stack end-to-end in linear protofilaments that interact laterally to form a cylindrical closed tube

approximately 25 nm in outer diameter ([Figure 2](#)). Microtubules are most commonly observed to have 13 protofilaments, but the number can vary by 1–2 protofilaments depending upon the environmental conditions, tubulin isoform, or the organism. Adjacent protofilaments are offset slightly such that the microtubule lattice typically has a left-handed helical pitch of 1.5 dimers per revolution ([Figure 2](#)). The parallel alignment of individual heterodimers results in an inherent polarity with α -tubulin monomers facing out at the minus-end and β -tubulin monomers facing out at the plus-end. Molecular motors, kinesins and dynein, recognize this polarity, exhibiting directional bias to move toward the plus- and minus-end, respectively.

Due to the cylindrical nature of the microtubule structure, individual tubulin subunits in the microtubule lattice interact longitudinally, within individual protofilaments, and laterally, between adjacent protofilaments. In the so-called 'B-lattice' structure (that most commonly observed), the majority of lateral contacts are between homologous subunits, i.e., α - α and β - β , except at the seam between protofilaments 1 and 13, where α - β contacts are made ([Figure 2](#)). These intersubunit interactions not only provide structural integrity but influence the microtubule assembly process as well. Intersubunit contacts are noncovalent, thus the binding of individual subunits is a reversible process. This has important consequences for the dynamics of self-assembly. First, binding and unbinding events are very rapid at typical free subunit concentrations (5–12 μ M), occurring in the order of milliseconds ([Gardner et al., 2011](#)). Additionally, microtubule self-assembly is highly dynamic and rapidly influenced by microtubule-binding compounds and intracellular microtubule-associated proteins (MAPs) that bind directly to microtubules.

Microtubule Self-Assembly Dynamics

Dynamic Instability

Microtubule self-assembly occurs by an unusual process termed 'dynamic instability,' in which individual microtubules

Figure 1 Examples of cellular processes that require dynamic microtubules.

stochastically switch between extended periods of growth and rapid shortening (Figure 3), while the average length of the microtubule population remains approximately constant (Mitchison and Kirschner, 1984). Growth is the net difference between association and dissociation of individual subunits, while shortening is dominated by rapid loss of subunits. The switch from growth to shortening is referred to as a 'catastrophe,' while 'rescue' is the reverse switch back to growth. The fact that dynamic instability is observed in purified *in vitro* assays demonstrates that it is an intrinsic property of microtubules, not dependent on MAPs, and is the result of subunit binding and unbinding, GTP hydrolysis in the lattice, and nucleotide exchange in solution.

Dynamic instability is a nonequilibrium process, driven by GTP hydrolysis (Figure 3). Initially, tubulin subunits have GTP bound to both α - and β -tubulin monomers. Hydrolysis occurs only at the exchangeable GTP binding site on β -tubulin

(E-site) while the non-exchangeable site (N-site) on α -tubulin remains bound to GTP (Carlier and Pantaloni, 1981). Because the molecule of GTP at the E-site is exposed at the plus-end, hydrolysis is coupled to polymerization, accelerating after an additional subunit binds longitudinally and closes the hydrolysis pocket at the terminal β -tubulin end (Nogales *et al.*, 1999, 1998). E-site GDP is exchanged for GTP after dissociation, but remains bound while the subunit is in the microtubule lattice. Within the microtubule lattice, GDP-tubulin is less stable, i.e., is shorter lived and unbinds rapidly due to less favorable intersubunit interactions. Thus, the microtubule tip assembly state, whether growing or shortening, is determined by the presence or absence, respectively, of a stabilizing cap of GTP-tubulin at the plus-end (Figure 3). Loss of the GTP cap, due to the combination of hydrolysis and the stochastic unbinding of GTP-tubulin, results in catastrophe and rapid disassembly while rescue occurs with the reformation of the GTP

Figure 2 Diagram of microtubule structure.

cap. Microtubules *in vitro* exhibit dynamic instability at both the plus- and minus-ends. However, *in vivo* the minus-end is typically associated with γ -tubulin containing nucleating structures that are often associated with centrosomes, such that assembly dynamics are largely mediated via the plus-end.

The experimental observation of dynamic instability only occurs in a relatively narrow range of free GTP-tubulin concentration near the critical concentration for growth, which is about 5–12 μM *in vitro* at physiological temperature (Walker *et al.*, 1988). Above $\sim 20 \mu\text{M}$ microtubules spontaneously nucleate and grow, further limiting the practical range of concentrations for *in vitro* experiments. Below the range where dynamic instability is observed, microtubules are unable to maintain growth and above they grow persistently as the more rapidly assembling plus-end outpaces GTP hydrolysis. Therefore, the observation of dynamic instability requires a balance between the net rate of subunit addition and the rate of GTP hydrolysis. When bound with a slowly hydrolyzing analog of GTP, GMPCPP, instead of GTP microtubules do not exhibit dynamic instability (Hyman *et al.*, 1992), further emphasizing the importance of hydrolysis and nucleotide exchange in addition to subunit addition and loss in the functional dynamics of microtubules.

Plus-End Tip Structures

In addition to the nucleotide state, structural features at the microtubule tip also correlate with growth and shortening (Figure 3), as observed using both electron and light microscopy. During growth, microtubules exhibit either tip

structures ranging from relatively blunt and straight conformations (the majority) to gradually tapering and gently radially curling extensions away from the closed tube (Chrétien *et al.*, 1995; Mandelkow *et al.*, 1991). During shortening, individual protofilaments peel away from the microtubule lattice in highly curled structures (Chrétien *et al.*, 1995; Mandelkow *et al.*, 1991; Tran *et al.*, 1997). This observation of the structural differences between growing and shortening microtubules led to the hypothesis that the energy of GTP hydrolysis is stored in the microtubule lattice as mechanical strain energy, due to constraining GDP-tubulin away from a preferred curled orientation in order to comply with the straight conformation of the microtubule lattice. This strain energy destabilizes the intersubunit interactions, causing GDP-tubulin to be less stable in the lattice than GTP-tubulin. Alternatively, observations that both GTP- and GDP-tubulin have a curled orientation in solution led to the recent hypothesis that subunits undergo a lattice-induced conformational change upon binding (Rice *et al.*, 2008). By this mechanism, GTP-tubulin must have stronger lateral contacts to resist curling in order to be consistent with observed structures by electron microscopy. In either case, GTP-tubulin is more stable within the lattice structure compared to GDP-tubulin, and thus GDP-tubulin rapidly disassembles when exposed at the plus-end (Figure 3).

Observations of microtubule plus-ends during growth by both electron and fluorescence microscopy are most consistent with a subset of protofilaments that extend out from the complete tube (Chrétien *et al.*, 1999; Demchouk *et al.*, 2011), which manifests itself as a tapered tip. More tapered tip structures form at higher free tubulin concentrations, where net assembly is fastest, while remaining primarily blunt at low concentrations (Chrétien *et al.*, 1995; Gardner *et al.*, 2011). At short time scales ($< 1 \text{ s}$), tip tapers fluctuate with the rapid addition and loss of individual tubulin subunits, although at longer time scales ($> 10 \text{ s}$) tip tapers on average increase in length during periods of growth (Coombes *et al.*, 2013). As a subset of protofilaments extends out from the closed tube, the number of stabilizing lateral contacts decreases, and therefore the average energetic state of tubulin subunits at the end of the microtubule becomes increasingly less stable. Thus, microtubule self-assembly dynamics are the result of an active interplay of the kinetics and thermodynamics of subunit addition and loss with the resulting polymer end structure. Subunit addition and loss results in fluctuating polymer end structures, which further feed back to determine the rates of addition and loss.

Cellular Microtubule Dynamics and MAPs

To observe single microtubule dynamics in living cells, light microscopy has been, and continues to be, the dominant approach. Transmitted light microscopy, combined with video processing to enhance image contrast, facilitated the earliest estimates of the dynamic instability parameters (growth rate, shortening rate, catastrophe frequency, and rescue frequency) *in vitro* and *in vivo* (Cassimeris *et al.*, 1988; Walker *et al.*, 1988), as well as early estimates of the rates of tubulin subunit addition and loss (Walker *et al.*, 1988). Since then, the

Figure 3 Microtubule self-assembly dynamics cover a wide range of length and time scales. At the atomistic level, groups of residues as well as the nucleotide state dictate the interdimer interactions (top, left). These interactions will influence the rate of addition and loss of individual subunits from the microtubule plus-end (top, right). The net result of addition and loss is dynamic instability (middle). Finally, dynamic instability facilitates microtubule function at the cellular level to mediate processes such as mitosis (bottom).

Figure 4 Microtubule assembly dynamics in LLC-PK1 epithelial cells. Individual microtubules are resolved near the cell edge (arrows). Below: kymograph (space-time) representation of fluorescence intensity along the length of individual microtubules showing dynamic instability in live cells.

development of sensitive digital cameras as well as better fluorophores, including genetically-encoded fluorescent fusion proteins, has made fluorescence microscopy the preferred approach for both *in vitro* assays with purified tubulin and in live cells. *In vivo*, areas with low microtubule density near the edge of relatively flat, thin cells facilitate the visualization and tracking of individual microtubules in time (Figure 4).

Compared to purified tubulin-based *in vitro* assays, microtubule dynamics *in vivo* are enhanced, exhibiting increased rates of growth and shortening as well as catastrophe and rescue. This is most likely due to the presence of cellular MAPs that influence the assembly and disassembly process, particularly those that are biased to associate with the dynamic plus-end, such as kinesin motors, end-binding proteins (EBs), and XMAP215. XMAP215 (ch-TOG in humans) is a plus-end

directed polymerization-promoting protein that increases the rate of both growth and shortening (Brouhard *et al.*, 2008). Kinesins and EBs both promote catastrophe despite opposite effects on the microtubule growth rate. Additionally, microtubules frequently undergo catastrophe as they grow against the cell edge. For the most part, *in vivo* microtubules grow persistently to the cell edge, where they undergo several rounds of catastrophe and rescue before rapidly shortening back to the nucleation point, typically the centrosome (Komarova *et al.*, 2002). This behavior allows dynamic interphase microtubules to explore the intracellular space, and accumulate in the longest directions, leading to spontaneous polarization of the microtubule array as occurs in neurons (Seetapun and Odde, 2010). During mitosis, the dynamics of microtubules facilitate chromosome-kinetochore ‘search-and-capture’ and subsequent chromosome segregation.

Additional MAPs including those that track growing plus-ends (e.g., CLIP-170) or bind to the microtubule lattice (e.g., tau and MAP2) influence microtubule assembly dynamics. EB1 recruits CLIP-170 and other plus-end tracking proteins (+TIPs) to the microtubule plus-end, which it recognizes via preferential binding of GTP-tubulin. Neuronal MAPs, tau and MAP2, stabilize microtubules, increasing the growth rate and rescue frequency while reducing shortening and catastrophe (Pryer *et al.*, 1992), thus enabling the substantial lengths of neuronal axons. Even though these MAPs associate with microtubules and influence assembly dynamics, they are not necessary to reproduce the increased dynamics observed *in vivo* compared to *in vitro*. Minimally, the combination of a polymerization-promoting protein (i.e., XMAP215) and a catastrophe promoter (i.e., kinesin), *in vitro* is sufficient to reproduce *in vivo*-like dynamics (Kinoshita *et al.*, 2001; Zanich *et al.*, 2013).

Overall, microtubule dynamics cover a wide range of length and time scales (Figure 3). At the atomistic level, groups of residues as well as the nucleotide state dictate the intersubunit interactions. These interactions influence the rate of addition and loss of individual subunits from the microtubule plus-end. The net result of subunit addition and loss, along with hydrolysis and nucleotide exchange, manifests in dynamic instability, which is necessary for microtubules to function at the cellular level.

Theoretical Framework for Microtubule Self-Assembly

With the development of more advanced instrument capabilities, as well as fluorescence imaging techniques, the amount of quantitative data available to the field has increased dramatically. The challenge now is to use this information to extract meaningful conclusions about complex biological systems. By integrating hypotheses and assumptions, theoretical models not only aid in understanding experimental results but can also be used to predict and design future experiments. In particular, with the rapid advances in digital computing, computational modeling has emerged as a useful tool for analyzing results and predictions, as well as hypothesis testing in cell biology, where systems are often complex.

The current kinetic-thermodynamic computational framework for microtubule self-assembly at the level of individual

Figure 5 Theoretical kinetic-thermodynamic framework for microtubule self-assembly. Examples of resulting microtubule plus-end structures are shown for multiple time points during the simulation (a–f). *Note:* preferential curling of tubulin subunits is not included in the basic framework shown. Lower right: zoomed view of microtubule assembly from simulation output shown above (blue box). The theoretical framework predicts the variability of microtubule self-assembly, including the observation of short periods of net disassembly during extended periods of overall growth.

subunit addition and loss is outlined in Figure 5 (Gardner *et al.*, 2011; VanBuren *et al.*, 2002), which derives from the earlier modeling of Chen and Hill (1985). In this framework, the rate of subunit addition to a single protofilament ($k_{\text{on,PF}}^*$ in units of $\text{s}^{-1}\text{PF}^{-1}$) is the product of the individual protofilament on-rate constant ($k_{\text{on,PF}}$ in units of $\text{M}^{-1}\text{s}^{-1}\text{PF}^{-1}$) and the concentration of tubulin subunits free in

solution ($[\text{Tub}]$, in units of M). The total number of addition events is then the sum of the individual protofilament on-rates ($k_{\text{on,MT}}^* = k_{\text{on,PF}}^* \times n_{\text{PF}}$, in units of s^{-1}). For individual subunits to ultimately bind to the microtubule lattice, subunits must diffuse to a close distance as well as orient correctly. This stereospecific constraint results in a very inefficient process such that the vast majority of free subunits that diffuse to

within a few nanometers of a potential binding site at the microtubule tip are predicted to fail to form a stable contact (Castle and Odde, 2013; Northrup and Erickson, 1992).

Once a contact with the microtubule lattice is established, the dissociation rate of individual subunits ($k_{\text{off,PF}}$ in units of s^{-1}) is determined by the sum of the longitudinal and lateral bond free energies ($\Delta G_{\text{long}}^{\circ}$ and $\Delta G_{\text{lat}}^{\circ}$ respectively), which are themselves a combination of the chemical interactions as well as the mechanical and entropic energies of constraining subunits within the microtubule lattice. The total bond free energy of GDP-tubulin subunits must be more positive, i.e., less stable, compared to GTP-tubulin in order for rapid disassembly to occur upon loss of the GTP cap. Of the two bonds, longitudinal bonds are approximately three-fold stronger than lateral bonds (Erickson and Voter, 1986; Sept *et al.*, 2003; VanBuren *et al.*, 2002). Because of this difference in stability, the longitudinal bond is required for subunit incorporation into the microtubule lattice, while the lateral bonds provide additional stabilization, largely reducing the rate of unbinding (Castle and Odde, 2013; VanBuren *et al.*, 2002). Subunits with increasing number of favorable interactions are more stable and dissociate several orders of magnitude slower than those with fewer favorable interactions. GTP hydrolysis is treated as a random (i.e., first-order) process, which occurs only after an additional subunit is bound longitudinally, stimulating hydrolysis at the E-site on β -tubulin. Consistent with a first-order process, the EB1 fluorescence signal, which preferentially binds GTP-tubulin, decays exponentially from the microtubule plus-end (Seetapun *et al.*, 2012).

This theoretical framework is sufficient to reproduce dynamic instability consistent with *in vitro* experimental observations and observations of dynamic microtubule end structures (Figure 5). Additionally, it captures the rapid nanoscale dynamics of assembly, including the high variability of assembly (Gardner *et al.*, 2011) as well as the observation of short periods of net disassembly during extended periods of overall growth (Schek *et al.*, 2007; Figure 5). Thus, the complex dynamics of microtubule dynamic instability, and self-assembly in general, naturally arise from these simple, physical principles.

Microtubule-Targeting Agents Attenuate Microtubule Dynamics

Microtubule-targeting agents (MTAs) are a diverse group of natural compounds and synthetic derivatives that bind microtubules and influence their self-assembly dynamics. In contrast to MAPs, which enhance microtubule dynamics, MTAs result in 'kinetic stabilization' or the attenuation of dynamic instability. The earliest noted MTAs include colchicine, the vinca alkaloids vinblastine and vincristine, and paclitaxel. MTAs are widely used chemotherapeutic options for the treatment of various types of cancer (reviewed in Dumontet and Jordan, 2010). This success stems from the fundamental role of microtubules in cellular processes (Figure 1), with a particular focus on the role of dynamic microtubules in mitosis. Additionally, MTAs have been used to treat gout (colchicine) and used in drug-eluting stents (paclitaxel) to prevent restenosis as a result of stent placement during the reopening

of occluded arteries. Further, the efficacy of paclitaxel in promoting axon regeneration to reduce spinal cord injury as well as potential for the treatment of neurodegenerative diseases is beginning to be explored.

MTAs bind directly to individual $\alpha\beta$ -tubulin heterodimers at three primary sites, which correlate with their effect on net polymer assembly. For the most part, disassembly-promoters bind to either the colchicine site at the intradimer interface between α - and β -tubulin monomers (Dorléans *et al.*, 2009) or the vinca domain at the terminal end of β -tubulin near the E-site (Gigant *et al.*, 2005). Colchicine site binders include the combretastatins in addition to colchicine, while vinca domain binders include the vinca alkaloids, dolastatins, and eribulin. Microtubule assembly-promoters bind to the taxane pocket, on the inside of microtubules near the lateral interface between adjacent dimers (Nogales *et al.*, 1999). Assembly-promoters include paclitaxel and its synthetic derivative, docetaxel, as well as the epothilones. This categorical assignment based on net assembly may be a bit misleading, however, as the effectiveness of all MTAs may ultimately depend on their capability to inhibit microtubule dynamic instability. Kinetic stabilization by MTAs increases the amount of time that microtubules spend in a non-dynamic 'paused' state, thereby eliminating cells' capacity to complete essential processes. As dynamic microtubules function in both mitotic and interphase cells, the side effects of MTAs are relatively frequent and often dose limiting. Most commonly, peripheral neuropathies occur during treatment, although additional side effects of bone marrow suppression and flu-like symptoms have been noted as well. MTA-induced kinetic stabilization is the culmination of the primary effects on individual tubulin subunit kinetics and thermodynamics at the molecular level (outlined in Figure 5). Therefore, further understanding the interplay between the microtubule self-assembly dynamics and microtubule structure may give us new insights into new and better-tolerated therapeutic strategies.

Glossary

Bistability Property of a dynamical system to have two stable states at a given parameter set. Bistable signaling cascades typically show either high or low activity in single cells at a given stimulus, thus allowing for binary decisions.

Hill coefficient Historically a coefficient in enzyme kinetics describing cooperativity, often used to quantify

ultrasensitivity of stimulus–response curves. Systems with Hill coefficients higher than one are ultrasensitive.

Oscillations Periodic changes in signal activity.

Sensitivity/logarithmic gain Relative signal amplification, defined as percent change in pathway activity divided by percent change in stimulus.

Ultrasensitivity A small relative change in signal elicits a large relative change in response, i.e., large logarithmic gain.

Introduction

Many signaling pathways are cascades of kinases, where one kinase activates the next by phosphorylation and thereby signals propagate through the protein network. Possibly the best-known and best-studied protein kinase signaling cascade is the mitogen-activated protein kinases (MAPK) signaling pathway, which serves as a paradigm of kinase signaling (Seger and Krebs, 1995). The core MAPK signaling pathway comprises three kinases: the MAP-kinase-kinase-kinase (MAP3K), which phosphorylates and thereby activates the MAP-kinase-kinase (MAP2K) that in turn activates the MAP-kinase by phosphorylation. This pathway is very well conserved among all eukaryotes. Human cells possess three major MAPK cascades (each having several isoforms), which are designated as extracellular regulated kinase (ERK), p38, and JNK pathways based on the name of their terminal cascade member (Dhillon *et al.*, 2007; Cargnello and Roux, 2011). The ERK signaling pathway has been implicated in the transmission of growth factor signals, while the p38 and JNK cascades play an important role in cellular stress responses (Dhillon *et al.*, 2007; Cargnello and Roux, 2011). Human cells also contain protein kinases cascades other than MAPK pathways: The PI3K-Akt signaling transmits growth factor signals like the ERK pathway, and has been implicated in cell division and cell survival control. The NF- κ B, SMAD, and the STAT pathways involve fewer steps than the classical MAPK cascade, as they involve only a single receptor-mediated phosphorylation event, which leads to nuclear translocation of a transcription factor.

During the last two decades, many studies have addressed the dynamics of MAPK kinase signaling (Kiel and Serrano, 2012). Mathematical models were employed to simulate the kinase kinetics and compared with quantitative experiments. In recent years, fluorescent techniques allowed for quantitative and time-resolved analysis of protein kinase signaling at the single-cell level (Nelson *et al.*, 2004; Cohen-Saidon *et al.*, 2009; Shankaran *et al.*, 2009; Colman-Lerner *et al.*, 2005). These studies have shed more light on the dynamical properties of protein kinase cascades. It is becoming clear that protein kinases cascades are very versatile in many aspects (Kholodenko *et al.*, 2010). When stimulated, they can generate

qualitatively different responses. For instance, a kinase cascade can show an oscillatory activation pattern, fluctuating between high and low activity states over time (Nelson *et al.*, 2004; Shankaran *et al.*, 2009). Alternatively, kinase cascades may establish cellular decision making by responding in a switch-like manner, once a threshold extracellular stimulus level has been exceeded (Huang and Ferrell, 1996; Ferrell and Machleder, 1998). Different extracellular stimuli often result in specific and qualitatively different intracellular responses, despite employing overlapping signaling pathways. It is believed that such specificity can arise, because each stimulus results in a quantitatively different activation pattern of the same signaling pathway (Purvis and Lahav, 2013; Ashe and Briscoe, 2006). However, how signaling pathways use the different dynamic activity patterns to relay signals is largely unknown and a subject of current research.

In the following we will provide an overview about three aspects of signaling dynamics: First, we will discuss how kinase cascades can amplify signals and help to make cellular decisions. Second, we will discuss different dynamic properties that are thought to relate to how kinase cascades encode information. Third, we will discuss mechanisms that kinase cascades employ to transmit signals in a robust and reliable manner (Figure 1).

Signal Amplification and Decision Making

Kinase cascades are composed of proteins that are controlled by two opposing processes that covalently modify the protein and its activity: Phosphorylation by upstream kinases and dephosphorylation by phosphatases (Goldbeter and Koshland, 1981). Such phosphorylation–dephosphorylation cycles are the basic units of kinase signaling, and the activity of each of the units represents a balance between the activity of the upstream kinase and the activity of the phosphatase.

Kinase cascades, such as the MAPK signaling pathway, can achieve remarkable signal amplification (Sauro and Kholodenko, 2004). Often, the presence of very low amounts of ligand can result already in the activation of a large amount of intracellular signaling proteins. For instance, just a few

Figure 1 Basic motifs of intracellular signaling and signal amplification. (a) The phosphorylation–dephosphorylation cycle. A target protein is covalently modified by phosphorylation. The phosphorylation and dephosphorylation reactions are catalyzed by opposing kinase and phosphatase enzymes, respectively. (b) Relative signal amplification and ultrasensitivity in protein kinase signaling. Relative signal amplification implies that a small fold-change in the input level induces a large fold-change in the response (‘ultrasensitivity’). The steep dose–response curves of ultrasensitive signaling cascades may establish switch-like cellular decision making (see text). (c) Ultrasensitivity arising from stoichiometric inhibition in protein kinase signaling. The inhibitor and the phosphorylated target protein form a 1:1 complex, implying that signaling is effectively blocked for low concentrations of the phospho-target protein. For higher kinase activities, the phospho-target protein concentration may exceed the inhibitor, and the signaling activity may increase in a switch-like manner.

epidermal growth factor (EGF) molecules in the medium are sufficient to activate about 100 000 ERK molecules, the target kinase in MAPK signaling. Such signal amplification is possible as each individual kinase can phosphorylate many substrate molecules. Typically, the percentage of how much target is phosphorylated is dependent on the balance of kinase activity and phosphatase activity, independently of the amount of target. Consequently, stronger expression of the target can result in more molecules to be activated. Thus, signaling cascades can ensure that cells can respond to minor amounts of stimuli.

Apart from amplifying the absolute signal, kinase cascades can also amplify relative signals, for example, a small relative change of the ligand concentration by 10% could result in a 30% change in the activity of the terminal cascade (Huang and Ferrell, 1996). The ratio of these two relative changes, i.e., the percentage by which the pathway responds divided by the percentage in which the initial signal changes, is often termed logarithmic gain. A very high logarithmic gain corresponds to a switch-like response of the kinase pathway, because a minor change in the ligand concentration may be sufficient to switch the target kinase from nil to complete activation (Figure 1(b)). Such switch-like signaling responses, also often referred to as ‘ultrasensitivity,’ have been implicated in cellular decision making (Ferrell, 1996).

It has been noticed that ultrasensitivity can be generated even in the basic unit of kinase cascades, i.e., in a phosphorylation–dephosphorylation cycle (Figure 1(a)). Ultrasensitivity requires that the kinase and the antagonizing phosphatase (catalyzing the dephosphorylation reaction) are strongly saturated by their target substrate (Goldbeter and Koshland, 1981). This type of ultrasensitivity has been termed zero-order ultrasensitivity, because the kinase or phosphatase enzymes have to work in the saturated zero-order regime (i.e., the enzymatic velocities are independent of the substrate concentration). Zero-order ultrasensitivity has been shown to be important switch-like MAPK signaling during embryonic development (Melen *et al.*, 2005). More recent work employing mathematical arguments, however, indicated that the enzyme concentrations in most kinase cascades are incompatible with zero-order ultrasensitivity, and cast doubt

that this is a general mechanism of switch-like decision making (Blüthgen *et al.*, 2006; Ciliberto *et al.*, 2007).

Another, possibly more robust, way by which kinase cascades could generate high logarithmic gain is multisite phosphorylation, i.e., when a kinase phosphorylates its target at multiple steps (Blüthgen and Herzog, 2003; Deshaies and Ferrell, 2001). For instance, a double phosphorylation mechanism implies that the concentration of the fully modified target may increase in a quadratic manner with the enzyme concentration (i.e., the logarithmic gain equals 2), (Thomson and Gunawardena, 2009). High logarithmic gains require that the two phosphorylation events occur in a distributed rather than processive manner, which means that the kinase detaches from its target after each phosphorylation (Salazar and Höfer, 2009). In MAPK signaling, both MAP2K and MAPK have to be phosphorylated at two amino acids to become activated. Whether this phosphorylation is indeed distributed or rather progressive is currently debated. While *in vitro* data clearly shows distributed phosphorylation (Burack and Sturgill, 1997), *in vivo* data remains conflicting and unclear (Aoki *et al.*, 2011; Schilling *et al.*, 2009; Toni *et al.*, 2012). It may be that scaffold molecules change the kinetics such that distributed phosphorylation becomes more processive if both kinase and target are on the same scaffold (Witzel *et al.*, 2012; Levchenko *et al.*, 2000). By doing that, scaffolds may modulate the logarithmic gain of a pathway (Bardwell, 2008).

A third way of generating high logarithmic gain is stoichiometric inhibition, where an inhibitor and its target protein form a reversible, signaling-incompetent 1:1 complex (Ferrell, 1996). Upon weak stimulation, this inhibitor may efficiently prevent cascade activation by strongly binding to a phospho-protein intermediate (Figure 1(c)). However, the cascade activity can increase in a switch-like manner upon stronger stimulation, because the concentration of the stimulus-dependent phospho-protein may at some point exceed the amount of inhibitor. Thus, the system suddenly switches from an inhibited to a non-inhibited regime (Ferrell, 1996; Buchler and Louis, 2008; Buchler and Cross, 2009). Experimental evidence for stoichiometric inhibition in MAPK signaling cascades is currently lacking. However, in other signaling pathways this mechanism has been shown to generate

ultrasensitivity (Kim and Ferrell, 2007), and in the context of gene regulation it is established that small RNAs can act as stoichiometric inhibitors for mRNAs that establish a switch-like gene expression response (Schmiedel *et al.*, 2012; Legewie *et al.*, 2008; Mukherji *et al.*, 2011).

Interestingly, the functional organization of phosphorylation-dephosphorylation cycles in multilevel cascades can increase the ultrasensitivity relative to the isolated cycles (Ferrell, 1997). Specifically, it has been shown that the logarithmic gain along a cascade is the product of the logarithmic gain of each individual levels (Brown *et al.*, 1997; Ferrell, 1996; Kholodenko *et al.*, 1997). If, for example, each level of the 3-tier MAPK signaling cascade had a logarithmic gain of 2 due to zero-order ultrasensitivity, the entire cascade would potentially have a logarithmic gain of 8. Then, a small change in the signal of for example 5% would result in a substantial, 40% increase in the activity of their terminal kinase.

Another mechanism for amplifying the logarithmic gain is positive feedback where, for example, a downstream kinase activates a kinase more upstream in the cascade by phosphorylation. Furthermore, if the feedback is strong, the system may exhibit bistability, which means that the pathway switches between discrete levels of activity as the stimulus is increased. Bistable systems also show history-dependent behaviors such as irreversibility: For example, if the pathway was strongly stimulated in the past, the pathway may stay highly active although the external stimulus is completely removed. This way, an irreversible cell fate decision and cellular commitment can be established (Bagowski and Ferrell, 2001; Bhalla and Iyengar, 1999; Legewie *et al.*, 2006, 2007).

Cellular Decisions Encoded in the Dynamics of Signaling

Information about the extracellular milieu is transmitted to the nucleus by a limited number of signaling pathways in mammalian cells. Given this limited number of structural components, it is not surprising that most signaling pathways have been implicated in the induction of diverse cellular responses. For example, the mammalian ERK-MAPK cascade is known to control the induction of various, often contradicting, cellular responses including cell proliferation, cell migration, cell death, and cell survival (Cargnello and Roux, 2011; Keshet and Seger, 2010; Dhillon *et al.*, 2007). Cells thus face a specificity problem, and the question arises of how the same signaling pathway is able to induce very different cellular responses in different cellular systems, and depending on the extracellular stimulus applied.

Recent research revealed how the same signaling pathway can elicit cell-type specific responses. One such mechanism is the compartmentalization of signaling: For the mammalian MAPK cascade it has been shown that nuclear translocation of the terminal kinase ERK is required for the induction of proliferation (Brunet *et al.*, 1999). Some cells express cytosolic anchors that prevent ERK from entering the nucleus (Formstecher *et al.*, 2001). ERK signaling is therefore unable to elicit a proliferation response in these cells, and the signaling effects are restricted to the cytosolic substrates of ERK. Cell-type specificity may further arise at the level of gene expression

networks located downstream of signaling. Protein kinase cascade typically induce covalent modifications in nuclear transcription factors, which in turn bind with cofactors to chromatin to drive gene expression. It was recently shown that cell-type specific gene expression responses to TGF-beta stimulation arise, because each cell-type expresses a specific set of cofactors that direct the common SMAD transcription factors to distinct sites in the genome (Mullen *et al.*, 2011).

Signaling specificity may also be achieved if the quantitative dynamics of signaling carry information about the cell fate. For instance, it was shown that the cytokine TNF-alpha activates multiple intracellular signaling pathways in parallel, and that the relative activation levels of these pathways determine how different cell types respond to the common stimulus (Miller-Jensen *et al.*, 2007). Likewise, it is also possible that the temporal activation profile of a single protein kinase cascade determines a cellular response. A classical example is the response of PC12 neuronal precursor cells to growth factor stimulation. These cells differentiate into mature neurons upon stimulation with neurotrophic growth factor (NGF), but divide if they are treated with EGF. Both ligands activate a broadly overlapping set of signaling molecules. However, NGF triggers a sustained activation of the ERK pathway, while EGF induces a transient ERK signaling. This finding led to the hypothesis signaling specificity is encoded in the duration of the ERK signal (Marshall, 1995). Experimental perturbations which affect the dynamics of ERK signaling support this claim: For example, a simple overexpression of EGF receptors prolongs the EGF-induced ERK signal, and switches the cellular response to EGF to differentiation (Traverse *et al.*, 1994).

The question arises of how two ligands like EGF and NGF that engage the same signaling pathway can elicit signaling with transient vs. sustained signaling in the same cell type. A mechanism that can convert a constant EGF stimulus into a transient signal is negative feedback (Cirit *et al.*, 2010), as depicted in Figure 2(a): the activity of the terminal kinase ERK promotes in the deactivation of the uppermost cascade member Raf. Thus, the system initially shows strong activation until the feedback inhibition results in downregulation of the signal (Figure 2(b), solid line). Interestingly, the feedback system can also show a switch from transient to sustained signaling if the stimulus strength is increased; for a sufficiently high stimulus, the feedback may no longer be strong enough to counteract and downregulate the cascade activity (Figure 2(b), dashed line; Behar *et al.*, 2007). This leads to a model where the number of cell surface receptors that can be activated by a ligand determines the duration of the downstream signaling, as supported by experimental studies (Traverse *et al.*, 1994).

Early theoretical work has suggested that differential negative feedback regulation by EGF and NGF may result in different signal duration and thus be the mechanism by which ligand identity is encoded (Brightman and Fell, 2000). A more recent experimental study further supported this hypothesis: Santos *et al.* (2007) systematically perturbed the MAPK cascade in PC12 cells by siRNAs against rapidly accelerated fibrosarcoma (Raf), MAP kinase or ERK kinase (MEK), and ERK, and used a modeling framework known as modular response analysis (Kholodenko *et al.*, 2002), to conclude that

Figure 2 MAPK signaling and encoding of information in the quantitative aspects of intracellular signals. (a) Negative feedback regulation in MAPK signaling. The core MAPK cascade consists of three kinases (Raf, MEK, and ERK) which are sequentially activated by phosphorylation on two or more residues. Negative feedback regulation arises, as the terminal kinase ERK triggers the hyperphosphorylation and thereby inactivation of Raf. (b) Negative feedback regulation can establish a switch from transient to sustained signaling with increasing input. Numerical simulations were performed for a simple negative feedback MAPK cascade (similar to panel A) for a low and a high concentration of the kinase catalyzing the phosphorylation of Raf ('low input' and 'high input,' respectively). The ordinary differential equation model is described in Behar *et al.* (2007) (Model IIIB; parameters values as described but $k_5=8e-1$).

EGF specifically induces negative feedback regulation in MAPK signaling. Furthermore, the authors showed that the MAPK signal upon NGF stimulation is amplified by a stimulus-specific positive feedback loop, which establishes a bistable and irreversible cell fate decision. However, other mechanisms are likely to contribute to the stimulus-specific signal duration as well. For example, it has been suggested that NGF receptors specifically engage the FRS adapter protein that shows sustained activation kinetics to trigger MAPK activation (Sasagawa *et al.*, 2005; Yamada *et al.*, 2004; York *et al.*, 1998). Sustained signaling via FRS may emerge, because this signaling protein continues to be active in the absence of active cell surface receptors, whereas adapter proteins recruited by the EGF receptor require ongoing receptor activity (Yamada *et al.*, 2004; York *et al.*, 1998).

If the stimulus-specific signal duration in PC12 cells underlies the cell fate decision between differentiation and proliferation, the cells must also be able to reliably distinguish (or decode) short and long MAPK signals. Duration decoding at the level of MAPK-induced gene expression has been analyzed in NIH3T3 cells, which behave different from PC12 cells, because they require a sustained MAPK signal for cell proliferation. Murphy *et al.* (2002) analyzed the immediate early gene c-Fos whose transcription is strongly induced very early after MAPK activation. The c-Fos protein functions as a transcription factor and is essential for triggering the expression proteins driving cell division. Murphy *et al.* found that Fos protein accumulation requires a sustained MAPK signal. This selective induction by a long MAPK signal could be explained by a phosphorylation-dependent stabilization of the Fos protein: The Fos protein is very unstable under normal conditions (half-life: 15 mins), but can be stabilized by ERK-dependent phosphorylation (half-life 4 h). Thus, Fos expression not only depends on early MAPK signaling (transcriptional induction), but also senses the late phase of ERK activity (posttranslational stabilization). Such a dual regulation of a target by a stimulus is known as a feed-forward loop and it has been suggested that these loops may generally allow gene expression networks to distinguish input of different durations (Shen-Orr *et al.*, 2002). The c-Fos network was recently analyzed in more detail by

Figure 3 Signaling features that determine cellular responses. Cell fate decision can be controlled by the duration of an intracellular signal, by its amplitude, or by the integrated response (also known as area under curve).

Kholodenko and colleagues using an experiment-theory approach (Nakakuki *et al.*, 2010). These authors concluded that the performance and robustness of duration decoding can be improved if the core feed-forward architecture is embedded in a more complex network, comprising additional feedback and feed-forward mechanisms. A recent study in NIH3T3 cells further suggested that these initial duration decoding mechanisms may be amplified further downstream in the gene expression network, because a long MAPK signal specifically triggered autocrine cytokine stimulation and a qualitatively different gene expression program (Toettcher *et al.*, 2013).

Information about the cellular fate may also be encoded in signaling features other than the signal duration (schematically depicted in Figure 3). A decisive feature in many signaling systems is the signal amplitude (Figure 3). A prominent example of amplitude encoding are spatial gradients of extracellular ligands ('morphogens') that control embryonic patterning: Along the gradient, these morphogens result in increasing activation of intracellular protein kinase cascades, and the signaling amplitude specifies into which cell type the tissue differentiates (Ashe and Briscoe, 2006). Another important signaling feature is the integrated response, also known as the area under curve (Figure 3; Schilling *et al.*, 2009;

Asthagiri *et al.*, 2000). For example, the proliferation of CFU-E cells in response to Epo stimulation is determined by the integrated response of the MAPK signal (Schilling *et al.*, 2009). In some cellular systems like NF- κ B, MAPK and Ca²⁺ pathways, it seems that the oscillation frequency of a signal encodes specific gene expression responses and cell fate responses (Albeck *et al.*, 2013; Purvis *et al.*, 2012; Hoffmann *et al.*, 2002; Dolmetsch *et al.*, 1998). Taken together, information that the cell uses for cellular decision appears to be encoded in a wide variety of signaling features (Purvis and Lahav, 2013). Future studies are required to better understand how quantitative signals can be robustly encoded and decoded by intracellular regulatory networks. To this end, experimental tools need to be developed to specifically assess the activities of kinases in subcellular compartments, because the signaling dynamics can be misinterpreted based on population-average measurements as measured in whole-cell lysates (Ahmed *et al.*, 2014).

Robustness of Signaling Pathways

For many signaling systems, it is essential to reliably and robustly transmit small changes in the input signal (Stelling *et al.*, 2004). One example for such a quantitative mode of signal transmission is the patterning process during animal development (Ashe and Briscoe, 2006) (see above). Such quantitative signal transmission is rather challenging, as signaling pathways have to deal with high amount of 'noise.' One of the main problems seems to be cell-to-cell variability in signaling protein expression levels; it has been observed that even clonal cells under the same condition express different amounts of each protein. Typically, cells expressing high levels of a given protein (95% percentile of the cell population) have an approximately threefold higher concentration of that protein when compared to the least expressing cells (5% percentile) (Cohen-Saidon *et al.*, 2009). This protein concentration variability is largely a consequence of so-called gene expression noise, which arises directly or indirectly from the stochastic nature of molecular processes involving small molecule number, such as in transcription and translation (Raj and van Oudenaarden, 2008; Elowitz *et al.*, 2002).

Several recent single-cell studies confirmed that, in many cases, protein expression noise is a major source of variability in intracellular signal transduction networks (Gaudet *et al.*, 2012; Yuan *et al.*, 2011; Spencer *et al.*, 2009; Feinerman *et al.*, 2008; Kollmann *et al.*, 2005). Theoretical considerations suggest that generic mathematical models of protein kinase cascades show strong variability of the signaling output if realistic protein concentration fluctuations are assumed (Jeschke *et al.*, 2013). Notable exceptions are ultrasensitive protein kinase cascades which can be intrinsically invariant despite varying protein concentrations in certain parameter regimes (Jeschke *et al.*, 2013). If these intrinsic robustness requirements are not met, a protein kinase cascade needs to be equipped with additional robustness mechanisms (like feedback or feed-forward loops) to allow for quantitative information transmission.

One simple strategy of noise suppression is the co-regulation of kinase and phosphatase expression (Feinerman *et al.*, 2008; Kollmann *et al.*, 2005). Typically, the activation level of a target

in a protein kinase cascade is dependent on the balance of kinase and phosphatase activities. Thus, the variability in the activation level can be buffered by making the fluctuations of the kinase and phosphatase expression levels correlated. Such a correlation implies that a cell with high kinase activity will also have a high activity of the antagonizing phosphatase, thereby compensating for imbalances in target activation. This principle has been shown to operate in the mammalian ERK cascade in T cells, where variability is suppressed, because the fluctuations of the CD8 receptor are highly correlated with fluctuations in the antagonizing phosphatase, SHP-1 (Feinerman *et al.*, 2008). At the gene expression level, correlated fluctuations may arise, because the kinase and the phosphatase expression levels are coordinately controlled by the same transcription factor. In fact, noise suppression by co-regulation of signaling proteins may be a wide-spread phenomenon: many eukaryotic signaling pathways are organized in so-called synexpression groups, that is, most of their components show tight spatio-temporal co-expression in different tissues of the body (Niehrs and Pollet, 1999).

Based on theoretical considerations, it has been speculated for some time that negative feedbacks could also help to buffer such variability in gene expression (Sauro and Kholodenko, 2004). Two recent papers used a combination of experiment and theory to show that negative feedbacks suppress the variability of MAPK and SMAD signaling (Paulsen *et al.*, 2011; Fritsche-Guenther *et al.*, 2011). For the case of MAPK signaling, it was shown that a strong negative feedback from ERK to RAF gives rise to concentration robustness: If MAPK/ERK expression levels were lowered by siRNA-mediated knock-down, ERK phosphorylation in colon cancer cells stayed approximately constant. Only if ERK expression dropped below ~50% of the original value, phospho-ERK decreased, implying that the robustness could no longer be maintained. Robustness in this pathway could be attributed to a feedback: When ERK protein concentration was lowered, activity of the upstream kinase MEK increased because negative feedback at the level of RAF was reduced. In cells with constitutively active RAF which also had disabled feedback, concentration robustness was lost (Fritsche-Guenther *et al.*, 2011).

Besides reducing the impact of protein concentration fluctuations, strong negative feedback also allows protein kinase cascades to more gradually respond to changes of the extracellular stimulus concentration (Jeschke *et al.*, 2013; Paulsen *et al.*, 2011; Sturm *et al.*, 2010). This implies that a negative feedback cascade is able to sense and to reliably transmit a larger range of extracellular stimulus concentrations when compared to a feedback-less cascade. Taken together, negative feedback optimizes the quantitative mode of information transmission in two ways: first, by allowing a more reliable transmission of a given input signal and, second, by extending the range of input signals that can be sensed.

Negative feedbacks can also have dramatic consequences on the efficiency of drugs to block the activity of signaling pathways. Particularly strong negative feedbacks, such as the ERK-RAF feedback tend to render the pathway robust against inhibition (Sturm *et al.*, 2010). It has for example been shown that MEK inhibitors are relatively inefficient, as strong feedback from ERK to RAF hyperactivates RAF and MEK when MEK is inhibited (Friday *et al.*, 2008; Fritsche-Guenther *et al.*, 2011).

Another important aspect of negative feedbacks in the context of targeted kinase inhibitors is that they can activate parallel compensatory pathways and can thereby render cells resistant against the pathway inhibitor. One example is the EGF receptor-RAS-RAF-MEK-ERK pathway in colon cells: The loss of a negative feedback from ERK to the EGF receptor upon MEK or RAF inhibition hyperactivates the EGFR. This leads to activation of a second kinase cascade downstream of the EGF receptor, the PI3K/AKT signaling pathway, which then causes resistance against RAF and MEK inhibition (Klinger *et al.*, 2013; Prahallad *et al.*, 2012). A similar mechanism mediates resistance in metastatic breast cancer. Here, a negative feedback from mTOR to IRS1 leads to activation of the JAK/STAT signaling pathway, when blocking the PI3K/AKT/mTOR cascade (Britschgi *et al.*, 2012). In both examples, co-inhibition of the parallel pathway was sufficient to re-sensitize the cells toward the inhibitor.

In summary, many if not most kinase cascades show negative feedback regulation, which likely evolved to provide signaling robustness and homeostasis; however, in the context of targeted therapies, such feedbacks were shown to mediate drug resistance.

Cdc42 and the Mechanisms of Yeast Cell Polarization – A Paradigm for Mesoscale Systems Biology

Introduction

Establishment of cell polarity is a fundamental process that is prerequisite for cell morphogenesis, migration, division, and differentiation. In most organisms studied to date, small GTPases play a central role in the regulation of polarity establishment. In bacteria, Ras-like proteins regulate accumulation of proteins at the cell poles and mediate bacterial motility (Keilberg and Sogaard-Andersen, 2014). In plant cells, members of the ROP (Rho-GTPases from plants) family drive polarization of tip-growing cells such as pollen tube or root hairs (Yang and Lavagi, 2012). In animal and fungal cells, The Rho-type GTPase Cdc42 is a highly conserved key regulator for the establishment of cell polarity (Harris and Tepass, 2010). The budding yeast *Saccharomyces cerevisiae* has proven to be an invaluable model system to unravel the molecular components and mechanisms underlying Cdc42-mediated polarity establishment. Early studies have identified many of the molecular components involved in cell polarization and have led to the proposal of a linear signaling cascade where stable cortical landmarks are interpreted through a series of molecular interactions that ultimately lead to local activation of Cdc42 and subsequent actin-mediated polarized growth (Drubin and Nelson, 1996). These studies were mostly based on genetic screens and the study of protein–protein interactions. In contrast, work in the last decade using a powerful combination of genetics, quantitative live cell imaging and theoretical modeling has revealed a complex system of interconnected feedback circuits that lie at the core of Cdc42-dependent symmetry breaking (Slaughter *et al.*, 2009b). In the course of deconstructing and manipulating these circuits, a considerable body of work on yeast polarity has accumulated that has since become a prime example of what has been poignantly defined as ‘mesoscale systems biology’ (Kirschner, 2005). The goal of this article is to summarize the key concepts in spatiotemporal cell organization that have emerged from work on yeast cell polarity regulation, with particular attention to the role and dynamic localization of Cdc42.

Cue-Dependent Cell Polarization

Saccharomyces cerevisiae cells divide through budding, a form of asexual reproduction in which a daughter cell or bud develops through localized growth and cell division. In haploid cells, new bud sites are always chosen adjacent to the previous site of division, leading to an axial budding pattern. In contrast, diploid yeast cells bud in a bipolar fashion. Importantly, cells division sites become permanently marked upon mother-bud separation and can be identified as birth scars in fresh daughter cells or bud scars in mother cells. Bud scars are characterized by a rigid, chitin-rich cell wall and several

integral plasma membrane (PM) proteins (Kang *et al.*, 2004). Classical genetic studies have identified two distinct pathways used by yeast cells to interpret bud scars as landmarks for cell polarization (Casamayor and Snyder, 2002). In both pathways, specific transmembrane proteins (Bud10 in haploid cells, Rax1 and Rax2 in diploid cells) are stably anchored to the cell wall at bud scars. These integral membrane proteins then interact with soluble cofactors (Bud3 and Bud4 for haploid cells, Bud8 and Bud9 for diploid cells) to recruit the guanine nucleotide exchange factor (GEF) Bud5. Bud5 recruits and activates the Ras-type GTPase Rsr1 (=Bud1), and the corresponding GTPase activating protein (GAP) Bud2 returns Rsr1 to its inactive GDP-bound form. Importantly, active Rsr1 together with the scaffold protein Bem1 can in turn recruit Cdc24, the only GEF for the central polarity regulator Cdc42. With the help of its GEF and several GAPs (Bem2/3, Rga1/2), Cdc42 exhibits the rapid activity cycles typical for small GTPases (Figure 1) and through several effector molecules (the PAK kinases Cla4 and Ste20, Gic1/2, the exocyst subunit Sec3 and the formins Bni1 and Bnr1) regulates downstream processes, including organization of the actin cytoskeleton, assembly of the septin ring at the bud neck and fusion of exocytic vesicles.

In combination these events ultimately drive polarized delivery of material and localized growth. The large number of molecular components involved in interpreting the spatial landmarks and establishing cell polarity can be simplified to a linear series of interactions between modules (Figure 2). The landmark is first interpreted by the bud site selection module (with Rsr1 at its center), which recruits and activates the Cdc42 module. Such series of connected GTPase modules can also be found in membrane transport processes where Arf and Rab GTPase are often organized in cascades (Jin *et al.*, 2011; Chesneau *et al.*, 2012). In its GTP-bound form, Cdc42 activates several effectors that finally lead to the polarized orientation of the actin cytoskeleton and oriented growth.

Haploid yeast cells exhibit a second type of polarization mode that occurs when cells of opposite mating type grow

Figure 1 Schematic of the GTPase cycle. GDP release and activation of the GTPase is mediated by guanine exchange factors (GEF), whereas GTP hydrolysis and inactivation of the GTPase is catalyzed by GTPase activating proteins (GAP).

Figure 2 Modular view of cue-dependent cell polarization. In this simplified linear view of polarization during yeast budding, each module (circle) encompasses several components and biochemical activities.

toward each other. The resulting pear-shaped shmoo fuse at their tips to form a diploid cell that then undergoes meiosis. The cue for mating cells is a gradient of secreted peptide pheromone that is recognized by G-protein coupled receptors on cells of the opposing mating type. As a consequence the associated trimeric G-protein dissociates and the $G\beta\gamma$ subunit recruits a Far1-Cdc24 complex to the cortex, where the GEF can locally activate Cdc42 and hence orient actin-based transport (Arkowitz and Bassilana, 2011). So while the initial cue and cue interpretation are distinct during budding and mating, the later steps of Cdc24 recruitment, Cdc42 activation and cytoskeleton polarization are conserved. The intersection of both pathways occurs on the level of the Cdc42 GEF. In addition temporal regulation of polarization also occurs through Cdc42 regulators. Cdk activity at the G1/S transition of the cell cycle leads to degradation of Far1, which keeps Cdc24 sequestered in the nucleus during G1 phase. This allows Cdc24 to move into the cytosol from where it can subsequently be recruited to the cell cortex via Rsr1 or Bem1 (Nern and Arkowitz, 2000). In addition, several Cdc42 GAPs have been shown to be phosphorylated by Cdk and thereby inactivated.

The example of cue-mediated polarization of yeast cells nicely illustrates a frequent phenomenon in cellular regulatory networks, where highly conserved core processes or core components (here the Cdc42 module) are linked to varying inputs through flexible linkages such as different GEFs/GAPs, inhibitors/sequestering factors or scaffolds. These ‘weak’ linkages together with the modularity of regulatory pathways constitute two central premises of the theory of facilitated variation (Gerhart and Kirschner, 2007), which explains the emergence of phenotypic variations from small genetic changes.

Breaking Symmetry

The genetic approaches that led to the identification of the components involved in cue-mediated cell polarization emphasized a linear and hierarchic development of cell polarity. However, most cells have the capacity to polarize in the absence of any positional cue or landmark, albeit in a random orientation (Kirschner *et al.*, 2000; Wedlich-Soldner and Li, 2003). This indicates that cells have an intrinsic ability to break symmetry that only depends on their internal biochemical state. Over the last decade, extensive experimental and modeling work has focused on the mechanisms for such spontaneous cell polarization and has identified fundamental features driving cellular morphogenesis. Yeast cell polarization

Figure 3 A simple positive feedback loop. Activated Cdc42 in the PM recruits or nucleates actin cables that in turn serve as tracks for transport of vesicles that bring more Cdc42.

and in particular the mechanism of Cdc42 polarization have played an important model role in this process. An initial key finding was that Cdc42 not only controlled actin organization but that Cdc42^{GTP} localization and accumulation in polarized regions in turn depends on actin-mediated transport (Figure 3).

Mathematical simulations based on this observation showed that simple amplification of stochastic variations in Cdc42 distribution through positive feedback can generate a polarized distribution of Cdc42 (Wedlich-Soldner *et al.*, 2003). Despite its simplicity, this initial model was able to make semi-quantitative predictions on the effects of transport speed or Cdc42 concentration, which could then be experimentally addressed. However, to allow a more realistic representation of cell polarization, some equivalent of the ‘long range inhibitor’ proposed in the classical pattern formation theory (Gierer and Meinhardt, 1972) needed to be included. A follow up study achieved this by introducing recycling of Cdc42 from the PM through endocytosis. In addition, quantitative values for model parameters were determined through live cell imaging. A particularly powerful experiment in this context is the measurement of protein mobility via fluorescence recovery after photobleaching. The resulting calculations of lateral diffusion rates for Cdc42 in the PM and the relevant association/dissociation times allowed predictions of the precise Cdc42 distribution during yeast polarity establishment based on a deterministic mathematical model (Marco *et al.*, 2007).

Both initial models for yeast polarization largely focused on the active, GTP-bound form of Cdc42. Cdc42^{GTP} is stably inserted into the membrane, and its distribution is dynamically determined by a balance of exocytosis, lateral diffusion within the PM and endocytosis (Figure 4). As both endo- and exocytosis require the actin cytoskeleton, Cdc42^{GTP} hence cannot polarize in the absence of actin structures. In contrast, wildtype Cdc42 rapidly cycles between its active and inactive forms, and this cycle is coupled to Cdc42 extraction from the membrane by Rdi1, the sole yeast member of the Rho-GDI (guanine nucleotide dissociation inhibitor) family (Tiedje *et al.*, 2008). GDIs can sequester the prenyl anchors present in Rho- and Rab GTPases and thereby extract them from membranes (Figure 4). Importantly this interaction is much more efficient for GDP-bound than for GTP-bound GTPases, leading to selective extraction of inactive Cdc42 (Johnson *et al.*, 2009).

Recent work, again combining quantitative imaging with genetic manipulations and mathematical modeling, has

demonstrated that GDI-mediated recycling of Cdc42 constitutes a second feedback loop that can drive efficient cell polarization (Slaughter *et al.*, 2009a). As this reaction involves cytosolic GDI-Cdc42 complexes, rather than the purely membrane bound Cdc42 in the actin feedback loop, the positive feedback in the system needs to be strong enough to counter the rapid spatial equilibration of soluble Cdc42. This is achieved by an elaborate mechanism: On the one hand GEF and GDI have been shown to compete for binding to Cdc42^{GDP}, which leads to preferential release of Cdc42 at sites of high GEF concentration. On the other hand active Cdc42 binds to the scaffold protein Bem1, which in turn recruits the GEF Cdc24 (Kozubowski *et al.*, 2008). In combination, these two reactions build a strong positive feedback loop that allows efficient accumulation of Cdc42 and spontaneous breaking of symmetry (Freisinger *et al.*, 2013). The Bem1/GDI loop has long been at the center of theoretical considerations on

symmetry breaking (Altschuler *et al.*, 2008; Goryachev and Pokhilko, 2008; Rubinstein *et al.*, 2012; Savage *et al.*, 2012; Klunder *et al.*, 2013). All models to date, whether stochastic and deterministic, were built around one or multiple positive feedback loops and were used to simulate distribution of Cdc42 and its direct regulators. Despite strong similarities in their fundamental assumptions the different models lead to very distinct outcomes. Validated by increasingly precise and quantitative experimental evidence the models became successively more detailed. This evolution of approaches at the interface of quantitative biology and theoretical sciences over the last decade can be seen as a paradigm for the study of cellular pattern formation. It is instructive to consider the different modeling approaches. When doing so, however, one should keep in mind that the value of mathematical models lies in their predictive power for a particular biological question, and this does not necessarily require inclusion of all known variables and interactions (Mogilner *et al.*, 2012). Rather on the contrary, simpler models have proven very effective in identifying key aspects of otherwise nonintuitive regulatory cycles.

Considering the existence of parallel pathways for Cdc42 recycling and polarization, the next challenge was to determine how the two feedback loops were coordinated in the cell. Again combining experiments and theory it was shown that only a combination of actin- and GDI-dependent recycling of Cdc42 allows yeast cells to establish robust cell polarity at a single site (Freisinger *et al.*, 2013). While the GDI pathway allows rapid recycling of Cdc42 and consistently generates a single-polarization site, it requires Cdc42 to cycle rapidly between its active and inactive form, and is therefore sensitive to perturbations of the GTPase cycle. Conversely, slower actin-mediated recycling of Cdc42 can induce robust symmetry breaking but fails to restrict polarization to a single site. These results suggest that cells optimize the efficiency of symmetry breaking by coupling multiple feedback loops with distinct properties (Figure 5).

Figure 4 Mechanisms for Cdc42 recycling. Cdc42 can be removed from the PM either by extraction through a GDI (1) or via actin-mediated endocytosis (2). Release from the GDI or recycling of membranes via exocytosis will then return Cdc42 to the PM.

Figure 5 A combination of feedback loops. The schematic depicts the various reactions and feedback loops that drive Cdc42 polarization during yeast budding. Rdi1 is the only yeast Rho-GDI. Bem1 interacts with the GEF Cdc24 and the PAK kinase Cla4. Formins are known to nucleate and elongate actin cables, while the Arp3/3 complex nucleates branched actin filaments that are required for formins. The exact biochemical link between Cdc42 and the actin nucleators is not yet clear.

Inhibitory Interactions and Reinforcements in Polarity Regulation

In the previous section different aspects of positive feedback were discussed, that allow budding yeast cells to spontaneously break symmetry and to establish cell polarity. In addition to these highly dynamic core processes involving rapid activity cycles and physical recycling of Cdc42, several additional mechanisms have been shown to either reinforce or counter Cdc42 polarization. These processes might be particularly important in maintaining or adapting a polarized growth pattern in the face of changing cell cycle regulation and constant exchange of material.

Work in the fission yeast *Schizosaccharomyces pombe* has highlighted the interplay between surface mechanics and polarity (Bonazzi *et al.*, 2014). During spore germination, the initial polarized region wanders around the surface and mediates isotropic growth. Outgrowth of a polar tube only occurs once the outer spore wall, which counteracts osmotic pressure, is ruptured at a single site. These results suggest that mechanical tension in the cortex can counteract cell expansion and thereby negatively regulate cell polarity. This effect is likely applicable to all cell walled cells. Even more generally, mechanical signals have been proposed to play a fundamental role in plant and animal polarization (Asnacios and Hamant, 2012).

In contrast to the proposed positive feedback loop involving vesicular trafficking of Cdc42, actin has been suggested to rather play an inhibitory role in polarity maintenance due to a net dilution of Cdc42 in the polarized region if vesicles fail to sufficiently concentrate Cdc42 (Layton *et al.*, 2011). A solution to these conflicting predictions came from studies showing that endocytosis and exocytosis are spatially segregated in the polar PM region (Jose *et al.*, 2013; Slaughter *et al.*, 2013) and that Cdc42 is actually enriched at sites of exocytosis, where it also exhibits slower lateral diffusion. Modeling indicated that nonuniform membrane diffusion of Cdc42 enables sustained cell polarity even at low concentrations of Cdc42 on vesicles (Slaughter *et al.*, 2013). Interestingly, Cdc42 microdomains are also enriched in the anionic phospholipid phosphatidylserine (PS), and PS was shown to contribute to the slow diffusion of Cdc42 (Slaughter *et al.*, 2013). A positive role for PS in establishment and maintenance of polarity was further supported by studies showing that Cdc42 localization was mediated by PS (Fairm *et al.*, 2011) and that the ratio between PS and the neutral lipid phosphatidylethanolamine regulates GDI-mediated recycling of Cdc42 (Das *et al.*, 2012a). As many of the regulators and effectors that bind to Cdc42 contain lipid binding segments, it is reasonable to assume that local lipid composition in the PM will affect many of the pathways and feedback loops regulating cell polarity. In this context it is important to note that the yeast PM has been shown to be segregated into a large number of overlapping microdomains (Spira *et al.*, 2012) through weak protein-lipid interactions. Together these results suggest that polarization or any spatial organization on the level of a whole cell may in fact originate from self-organization mechanisms on the level of individual protein-membrane complexes.

Positive feedback is sufficient to explain the spontaneous emergence of a single polarity site. However, when observing

the development of polarized sites over longer time scales phenomena such as competing, wandering or oscillating polarity sites have been reported, which indicate the presence of additional negative feedback (Wedlich-Soldner *et al.*, 2004; Ozbudak *et al.*, 2005; Howell *et al.*, 2012). An exciting mechanism for such negative regulation could occur through inhibitory phosphorylation of the GEF Cdc24 via the Cdc42-activated PAK kinase Cla4 (Kuo *et al.*, 2014). This scenario constitutes a prime example of an incoherent feedforward loop (Hart and Alon, 2013) built on the activities of Bem1. This scaffold protein binds directly to active Cdc42, Cdc24 and to Cla4. On the one hand binding of Bem1 to Cdc24 relieves the latter's autoinhibition and recruits it to its target, Cdc42. On the other hand the recruitment of Cla4 leads to a delayed phosphorylation and thereby inactivation of Cdc24. Such counteracting – or paradoxical – activities are frequently used by cellular regulatory modules to achieve robustness of a response against fluctuations in the concentration of individual regulators (Hart and Alon, 2013). While incoherent feedforward loops cannot generate oscillations on their own, they would be able to do so in combination with positive feedback, which is clearly present in polarizing yeast cells (Kuo *et al.*, 2014). A similar mechanism centered on delayed negative feedback has also been put forward to explain oscillatory polarization of fission yeast cells (Das *et al.*, 2012b).

A different kind of negative feedback has been recently proposed to act through septins. It has been well established that Cdc42 can recruit septins directly and via the yeast specific effector proteins Gic1 and Gic2 (Sadian *et al.*, 2013). Septins in turn are able to recruit the Cdc42 GAP Bem2, which leads to a delayed inactivation of Cdc42 at sites of septin assembly. An interesting twist to this story is that Cdc42-driven exocytosis likely leads to displacement of septin polymers from the center of the polarized region and thereby supports formation of the septin ring (Okada *et al.*, 2013).

A final type of polarity regulation centering on GTPase signaling concerns inhibitory landmarks that prevent recruitment of Cdc42 sites of previous cell division. On the one hand the Cdc42 GAP Rga1 establishes an exclusion zone at the division site that blocks subsequent polarization within that site (Tong *et al.*, 2007). In addition a protein complex that competes for Cdc24 binding to Cdc42 is permanently anchored at bud scars and thereby serves as negative memory for polarity establishment (Meitinger *et al.*, 2014). Both of these mechanisms constitute static zones of occlusion and therefore provide a distinct approach to polarity regulation compared to the dynamic concentration of Cdc42 typical for the feedback regulation discussed before.

In summary, small GTPases constitute central regulators for spatial organization in cells. Rho-GTPases and in particular Cdc42 are key regulators of the actin cytoskeleton and of cell polarization. Studies on Cdc42-mediated cell polarization have been at the forefront of mesoscale systems biology approaches that combine quantitative imaging techniques with molecular perturbations and mathematical models. A large number of yeast studies in the last decade have constantly pushed our understanding of the fundamental principles underlying cell polarity establishment and maintenance – and are still providing surprising new insights. The concepts and techniques developed in these studies have since been

picked up in many other fields and have led to a dramatic increase in our appreciation of the self-organization properties of cellular circuits. The coming years will see a further rapid expansion of our quantitative repertoire – both technical and theoretical. The next big challenge will be to now transfer the gained knowledge into creation of minimal or synthetic systems.

Introduction

Any eukaryotic cell transports nutrients and signaling molecules, here collectively called cargo, between its plasma membrane and intracellular target compartments (Mellman, 1996). Receptor-mediated endocytosis, through inward budding of clathrin-coated vesicles (CCV) or clathrin-independent vesicles, provides the means for selective cargo uptake (Conner and Schmid, 2003). This endocytic cargo uptake inevitably is coupled to membrane and receptor uptake. Immediate delivery of the many small uptake vesicles to target compartments would risk a large membrane and receptor loss at the price of resynthesis. A solution to this unfavorable consequence of coupled cargo and membrane trafficking is the intermediate accumulation of like cargo and recycling of membrane and a specific set of receptors to the plasma membrane (Sheff *et al.*, 2002; Lauffenburger and Linderman, 1993). Early endosomes (EEs), i.e., several hundreds of intermediary vesicles per cell, fulfill this essential accumulation and sorting function (Figures 1(a) and 1(c)). EEs constitutively undergo homotypic fusion and fission among them and as a whole constitute the endosomal network of dynamically interlinked vesicles (Gruenberg and Maxfield, 1995; Collinet *et al.*, 2010).

There is an intriguing question regarding the overall performance of the endosomal network. As the endosomal network is fueled by small uptake vesicles and homotypic fusion and fission occur more or less randomly given heterogeneous cargo mixtures and their noisy perception, how could endosomes carrying large amounts of cargo be produced for more efficient cargo delivery to target compartments? In quantitative terms, the size distribution of the EEs should possess a broad tail as does a power law distribution (Figures 1(b), 1(d), and 1(e)).

The individual EEs operate independently of one another and have no information on the overall cargo distribution. Such a power law relation is characteristic for many complex systems (Ziemelis, 2001). Nontrivial collective properties can emerge at the scale of the whole endosomal network (here called the macroscopic level) that are not imposed explicitly at the level of the system components (the microscopic level). Repeated interactions among the components let the collective properties emerge or self-organize.

An additional tool that provides important insights is a theory of the endosomal network in which the details of single endosome interactions are described by mathematical terms and the collective effects of many such interactions can be analyzed using mathematical methods. Once having linked microscopic to macroscopic properties through a theory then one can also use it as a means to infer microscopic properties that are not directly observable from readily observable macroscopic properties. We review such a theory as developed by Foret *et al.* (2012) in the following Section 'General Model'

and progress with its analysis for the particular case of low-density lipoprotein (LDL) trafficking in HeLa cells in Section 'Entry-Fusion-Exit Model.' The comparison to experimental data confirms the theoretical predictions and lets one estimate the microscopic parameter values. In subsequent sections, we describe selected mechanisms for regulating endosome interactions and discuss how they refine cargo and membrane trafficking.

Theory of the Endosomal Network

General Model

Cargo distribution in a population of endosomes

At a given instant t , each endosome contains a certain amount of cargo (i.e., number of cargo molecules), see Figures 1(a) and 1(c). The overall population is characterized by the distribution of cargo defined as the number $n(s,t)$ of endosomes loaded with a number s of cargo molecules. Repeated interactions between endosomes and with other cell organelles result in the continual redistribution of the cargo in the population and thus lead to the evolution of $n(s,t)$ overtime. For example, when an endosome with 15 cargo molecules fuses with an endosome with 6 cargo molecules, these two endosomes disappear (then $n(15)$ and $n(6)$ decrease by one) and a new endosome with 21 cargo molecules appears ($n(21)$ increases by one). The profile of the distribution $n(s,t)$ and the way it evolves directly reflect the underlying dynamics of the many individual endosomes. The goal of the theory is to predict the emergent macroscopic behavior of $n(s,t)$ from the microscopic interaction processes at the single endosome level such as fusion and fission.

Microscopic processes and parameters

Only six basic processes can modify the cargo distribution in the endosome population. They are sketched in Figures 2(a)–2(f) and any other process would involve three or more simultaneously interacting endosomes, which is negligibly rare. The homotypic fusion of two endosomes loaded with the cargo amount s and s' , respectively, leads to the disappearance of these two endosomes and to the formation of a new endosome containing $s + s'$ cargo (Gorvel *et al.*, 1991; Gruenberg and Maxfield, 1995; Rink *et al.*, 2005; Rybin *et al.*, 1996), see panel (c) in Figure 2. Homotypic endosome fission (d) is the reverse process: two new endosomes with the cargo amount s and s' arise from a single endosome containing $s + s'$ cargo (Bonifacino and Glick, 2004; Rink *et al.*, 2005; Skjeldal *et al.*, 2012). Beside these internal exchanges among individuals within the population, the endosome population receives and delivers cargo from and to other cell organelles by means of the four processes (a), (b), (d), and (e), but no other.

Figure 1 Quantification of endosome distributions *in vivo* and *in vitro*. (a) Fluorescence microscopy image of a mouse liver section stained for EEA1 (together with phalloidin (green) and DAPI (blue)), marking early endosomes (EEs) as magenta objects in hepatocytes *in vivo*. (b) Cargo distribution in early endosomes on lin-log scales (black curve for normal liver) with cargo amount s after 20 min of internalizing labeled LDL. Perturbation of regulatory components of the endosomal network changes the cargo distribution *in vivo* (red curve for liver-specific Rab5 knock-down). (c) Fluorescence microscopy image of HeLa cells *in vitro* expressing GFP-Rab5 (green), loaded with labeled LDL cargo (red) and stained by DAPI (blue). (d, e) Cargo distribution in early endosomes on lin-log (d) and log-log (e) scales. The broad tail (with a power law contribution) of the distribution is the hallmark of cargo accumulation through many rounds of homotypic EE-EE fusion and membrane recycling. Individual colors refer to different time points after adding labeled LDL cargo to the culture medium. FI and FI' are microscope-specific units of cargo fluorescence intensity. Scale bars are 20 μm in (a) and 30 μm in (c). (a) and (b) are adapted by permission from Macmillan Publishers Ltd: Zeigerer, A., Gilleron, J., Bogorad, R.L., *et al.*, 2012. Rab5 is necessary for the biogenesis of the endolysosomal system *in vivo*. *Nature* 485, 465–470, copyright (2012). (c)–(e) are reprinted from Foret, F., Dawson, J.E., Villaseñor, R., *et al.*, 2012. A general theoretical framework to infer endosomal network dynamics from quantitative image analysis. *Current Biology* 22, 1381–1390, copyright (2012), with permission from Elsevier.

Cell organelles are able to abruptly and irreversibly change their nature by a rapid modification of their biochemical composition. This process is called maturation, or sometime conversion. Non-endosomal structures can convert into endosomes and conversely endosomes can convert into organelles of another type. For example, endocytosed vesicles may convert into early endosomes (Conner and Schmid, 2003; Gruenberg and Maxfield, 1995) while early endosomes can convert into late endosomes (Rink *et al.*, 2005; Del Conte-Zerial *et al.*, 2008; Poteryaev *et al.*, 2010). Conversion of a cargo-filled vesicle into an endosome is equivalent to the creation (biogenesis) of a new endosome with the same cargo amount as the original object (a). On the other hand, conversion of an endosome into another structure is equivalent to the removal of this endosome (and its cargo) from the population (f). Finally, individual endosomes can receive and release cargo by means of heterotypic fusion (b) and heterotypic fission (e), respectively. A heterotypic fusion event with a cargo-loaded vesicle results in the growth of the cargo amount in that endosome. The budding and scission of a vesicle or tubule decreases the cargo amount in the parent endosome but neither of these two processes changes the total number of endosomes. (a)–(f) is the exhaustive list of events able to affect the cargo distribution in an endosome network. However,

depending on the type of endosomes and on the type of cargo, not necessarily all six processes are active.

The six events (a)–(f) occur repeatedly in an apparently stochastic manner driving the evolution of the population. The probability that a fusion of two endosomes with cargo amount s and s' occurs in the short time interval dt is $n(s)n(s')K(s,s')dt$; it is proportional to the numbers of endosomes with s and s' cargo amount and to dt . The coefficient $K(s,s')$ is the fusion rate, whose value depends on the molecular details of the protein machineries responsible for endosome motility, tethering and membrane fusion. The theory at the endosome scale does implicitly include such details through the fusion rate $K(s,s')$. It is a function of s and s' since the cargo load could indirectly regulate the fusion machinery favoring or preventing fusion. In the same manner, we can define five more rates characterizing each of the processes (a)–(f) of Figure 2. The probabilities associated to the occurrence, during dt , of the other events as ordered in Figure 2 are $A(s)dt$, $v_{in}(s)n(s)dt$, $n(s+s')K'(s,s')dt$, $v_{out}(s)n(s)dt$ and $k_d(s)n(s)dt$ with $A(s)$ the *de novo* creation rate, $v_{in}(s)$ the cargo absorption rate, $K'(s,s')$ the fission rate, $v_{out}(s)$ the cargo release rate, and $k_d(s)$ the conversion rate. The six rate functions are the context-specific input of the theory. Given these parameters, the goal is to calculate $n(s,t)$.

Figure 2 There are six principle processes of endosome interactions. Here these are ordered according to their sequence during cargo transport (red symbols). Green (blue) symbols denote membrane-associated proteins, such as Rab5 (Rab7), which confer functional specificity to endosomes. See Section ‘Microscopic processes and parameters’ for details on individual processes (a–f). Reprinted from Foret, F., Dawson, J.E., Villaseñor, R., *et al.*, 2012. A general theoretical framework to infer endosomal network dynamics from quantitative image analysis. *Current Biology* 22, 1381–1390, copyright (2012), with permission from Elsevier.

Governing equation

Having chosen the parameters (the six rates) and an initial state of the endosome population of a cell, one can simply simulate the stochastic evolution of $n(s, t)$ by repeatedly using the probabilities for each process to occur within short-time intervals. Such a stochastic simulation can be efficiently performed using the Gillespie algorithm (Cao *et al.*, 2004; Mukherji and O’Shea, 2014). Simulating the evolution several times and averaging, one can compute the evolution of the mean $n(s, t)$ that can be compared to experimental data.

Another approach is to derive a mathematical equation satisfied by the mean $n(s, t)$. Because of the large number of endosomes in a population, a kinetic equation similar to those used in chemical kinetics describes the evolution of the mean $n(s, t)$. It reads:

$$\begin{aligned}
 \frac{\partial n(s)}{\partial t} = & \frac{1}{2} \int_0^s K(s', s-s') n(s-s') n(s') ds' \\
 & - \int_0^\infty K(s', s) n(s) n(s') ds' \\
 & + \int_0^\infty K'(s, s') n(s+s') ds' \\
 & - \frac{1}{2} \int_0^s K'(s-s', s') n(s) ds' \\
 & + A(s) - k_d(s) n(s) - \frac{\partial}{\partial s} [v_{in}(s) n(s)] \\
 & + \frac{\partial}{\partial s} [v_{out}(s) n(s)]
 \end{aligned} \quad [1]$$

Note that in order to make the mathematical analysis of the equation simpler, we have considered the cargo amount s as a continuous variable. It follows that $n(s)$ is a number density, $n(s)ds$ being the mean number of endosomes with a cargo amount between s and $s+ds$ for a vanishingly small ds . An analogous approach is used to describe coagulation of particles in physics (Smoluchowski, 1916; Hogg *et al.*, 1966). Each term of the equation gives the average number of endosomes with s cargo created or lost per time unit due to one of the six basic processes, with fusion and fission requiring two terms each. The merit of this approach is that exact or approximated mathematical solutions can be found for simple forms of the parameters. This allows us to gain mechanistic understanding of the contribution of each microscopic process to the macroscopic property $n(s, t)$ and on the way how it evolves.

Entry-Fusion-Exit Model

Let’s now apply the theory to predict the features of the distribution of cargo $n(s)$ for a simple set of parameters. Consider a hypothetical population in which new endosomes with small cargo amount s_0 appear at the rate $A=J/s_0$ (J is the cargo influx), fuse at the constant rate K and convert at the constant rate k_d . Fissions (Figures 2(d) and 2(e)) and heterotypic fusion (b) are not included (their rates are set to zero). The endosome population is initially devoid of cargo. We refer to this choice of parameters as the ‘entry-fusion-exit model’ of endosome dynamics.

Theoretical predictions

In this simple model, the evolution of the total number $N = \int_0^\infty n(s)ds$ of endosomes in the population is governed by the equation,

$$\frac{dN}{dt} = \frac{J}{s_0} - \frac{KN^2}{2} - k_d N \quad [2]$$

From here on, we consider that fusion events are much more frequent than conversion events. Then the solution is approximately

$$N(t) = \sqrt{2J/Ks_0} \tanh\left(\sqrt{JK/2s_0} t\right) \quad [3]$$

At early times, while the number of endosomes is small, fusion (and conversion) is very rare, the number of endosomes rises as $N(t) = (J/s_0)t$. After some time, the number of fusion events and *de novo* creation events balance each other and the number of endosomes stays nearly constant at $N(t) = \sqrt{2J/Ks_0}$.

We now turn to the behavior of the full distribution $n(s,t)$ in the entry-fusion-exit model. Its evolution can be divided into three phases. In the first phase, the distribution $n(s,t)$ peaks at s_0 and its height $n_{\max}$ behaves as the total number of endosomes, $n_{\max}(t) = (b/s_0)N(t)$ with b a numerical prefactor. It rises until fusion balances *de novo* creation. In the second phase, fusion events produce endosomes accumulating more and more cargo. The distribution $n(s,t)$ broadens more and more over time. In the third phase, endosome conversion curbs the growth of endosomes and yields a steady state: $n(s)$ does no longer evolve in phase 3. Mathematically, beyond the peak at s_0 and during the phases 2 and 3, the distribution is approximately

$$n(s) = \sqrt{J/2\pi K} s^{-3/2} \exp\left(-s/s^*(t)\right) \quad \text{with} \quad s^*(t) = \begin{cases} JKt^2 & \text{for } t \ll 1/k_d \\ 2JK/k_d^2 & \text{for } t \gg 1/k_d \end{cases} \quad [4]$$

The cargo distribution decays slowly as a power law $n_s(s) \sim s^{-3/2}$ up to a cargo value s^* beyond which the decay is abrupt. This maximal cargo load s^* increases with time during the second phase and finally saturates at a constant value in the third phase. This evolution is called ‘self-similar’: as time progresses, $n(s,t)$ gets ‘stretched’ along the s axis until its final steady state profile.

These results illustrate how the mathematical analysis of the equation allows us to understand the effect of each basic process on the shape of $n(s,t)$. Comparing these predictions to experimental data, one finds that already the simple entry-fusion-exit model very accurately describes the trafficking of LDL cargo in HeLa cells.

Comparison of theory predictions to LDL trafficking in HeLa cells

Analyzing fluorescence microscopy images (labeling an early endosome marker and cargo), one can detect endosomes, measure for each of them their cumulative cargo fluorescence which corresponds to the cargo amount s and then deduce the distribution $n(s)$, see Figure 1. In an interesting experiment, HeLa cells stably expressing Rab5-GFP as early endosome marker were placed in a medium containing fluorescent LDL cargo. The distribution of LDL amounts in Rab5-endosomes

was then measured at different times after the cells started to endocytose LDL. Figures 1(e) and 1(f) show that the experimentally measured cargo distributions qualitatively validate the prediction by the entry-fusion-exit model: a peak at small s rises and saturates during the first 10 min (phase 1) and on a longer time scale, the distribution progressively broadens and apparently stretches along the s axis (phase 2), it finally reaches a stationary state after 30 min (phase 3). Beyond this qualitative agreement, the data reproduced in Figure 1 bear all the mathematical features predicted in the preceding section. The evolutions of the height of the distribution’s peak $n_{\max}$ and of the total number of endosomes N are very well fitted by the law [3], see Figures 3(a) and 3(c). In Figure 3(b), the distributions at different times where plotted on a rescaled axis with an s^* chosen for each time such that the distribution tails overlap. Beyond the peak, all the curves fall onto the same curve, which is the function $x^{-3/2} \exp(-x)$ shown as solid line in Figure 3(b). This data collapse confirms the self-similar nature of the evolution and the accuracy of the predicted solution [4]. Moreover $s^*(t)$ obtained by the curve rescaling evolves as predicted in eqn. [4]: it first grows with time as t^2 and reaches a plateau after 30 min (inset in Figure 3(b)).

In order to further test the predictions, one would like to experimentally tune some parameters. Changing the concentration of LDL in the cell culture medium results in the change of the LDL influx J into each cell and thus into the early endosomal system. The value of J can be easily deduced from the evolution of the total LDL fluorescence of the cell. The experiments were repeated using 4 different values of J . The evolution of $N(t)$ in the four cases is shown in Figure 3(c). When plotting $N/\sqrt{J}$ as a function of $\sqrt{J}t$, all the curves once again overlap as predicted by eqn. [3], Figure 3(d).

What do we learn?

Quantitative comparison between experimental data on the entire endosome population and the theoretical predictions allows us to reach unbiased conclusions regarding the organization of the early endosomal system. Degradative cargoes such as LDL that enter the cell in many small structures are progressively concentrated in a few large endosomes by the mean of repeated random fusion and finally sent to the late endosomal system by conversion of early endosomes. Another scenario that one may propose after qualitative observations would lead to a markedly different profile and evolution for $n(s,t)$ and can thus be ruled out. Analogously, the data are only compatible with a constant fusion rate since otherwise the distribution features would be different (see Foret *et al.*, 2012 for details). It indicates that LDL is a passive cargo weakly affecting the fusion machinery. A fit of the data yields the values of the microscopic parameters (entry rate, fusion rate, and conversion rate) that are difficult to measure directly. The success of the entry-fusion-exit model does not mean that fission and heterotypic fusion do not exist but it means that they should have a small influence on the distribution of LDL cargo in early endosomes of HeLa cells.

Regulation of the Microscopic Processes

Cargo molecules change their receptors’ activation state through binding and unbinding which itself is affected by

Figure 3 Experimental verification of the theory of cargo trafficking in the endosomal network. (a) Maximum values of the cargo distributions shown in Figure 1(d) as function of time (symbols) verify the theory prediction (solid curve) by eqn. [3]. (b) Rescaled cargo distributions (symbols) from Figure 1(e) collapse on the predicted universal curve shape (eqn. [4]). The scaling parameter s^* (inset) is correctly predicted by eqn. [4], the parabolic limit of the prediction for short times is shown as solid line, the saturation is also correctly predicted. (c) The dependence of the total number of cargo-filled early endosomes on time and medium composition (see legend) is correctly predicted (dashed curves) by eqn. [3]. (d) Rescaling of the data from panel (c) with the predicted influx dependency collapses all data onto the universal time dependency as predicted by eqn. [3]. Reprinted from Foret, F., Dawson, J.E., Villaseñor, R., *et al.*, 2012. A general theoretical framework to infer endosomal network dynamics from quantitative image analysis. *Current Biology* 22, 1381–1390, copyright (2012), with permission from Elsevier.

cargo accumulation within individual endosomes and by gradual acidification of the endosomal lumen (Lauffenburger and Linderman, 1993). The receptors' cytoplasmic domains can transmit the binding signal to effector proteins with guanine nucleotide exchange (GEF) and GTPase-activation (GAP) activities (Tall *et al.*, 2001). Small GTPases of the Rab family act as master regulators of the endocytic protein machinery and can integrate the cargo-dependent GEF and GAP activities with other signals (Zerial and McBride, 2001). For EEs, the GTPase Rab5 plays this central role and increased Rab5 activity fosters cargo uptake (Zerial and McBride, 2001), homotypic EE fusion (Ohya *et al.*, 2009), homotypic EE fission (Zeigerer *et al.*, 2012) and, surprisingly, also EE to late endosome conversion (Rink *et al.*, 2005; Del Conte-Zerial *et al.*, 2008; Poteryaev *et al.*, 2010). The activation of the reciprocal microscopic processes fusion and fission by Rab5 conveys robustness to macroscopic properties such as total endosome number as demonstrated in an integrated theoretical and experimental study of Rab5 titration in hepatocytes

(Zeigerer *et al.*, 2012). Different cargo types may affect Rab5 differently through their specific co-transported receptors. For example the cargoes EGF and LDL have been observed to differently modulate the macroscopic properties of the endosomal network (Collinet *et al.*, 2010). In the theory presented above, the transport of different cargoes can be modeled by readjusting the parameter values for the rates of the microscopic processes. The regulatory functions of certain cargoes as well as possible dependencies of the microscopic processes on the physical size of the endosomes can in the theory be accounted for by the s -dependencies and additional time-dependencies of the six rate functions, see Section 'Microscopic processes and parameters.'

Relation to Kinetics of Total Cargo Pool

The total cargo content $\Phi(t)$ per cell can be obtained from the cargo distribution $\Phi(t) = \int_0^\infty sn(s,t)ds$. The total cargo

influx J into the endosomal network is $J(t) = \int_0^\infty (sA(s,t) + v_{in}(s,t)n(s,t))ds$. A general kinetic equation for $\Phi(t)$ can be derived from eqn. [1] by multiplication with s and integration of both sides of the equation:

$$\frac{d\Phi}{dt} = J(t) - \int_0^\infty (k_d(s,t)sn(s,t) + v_{out}(s,t)n(s,t))ds. \quad [5]$$

Only in special cases with $k_d(s,t) = \text{const}$ and $v_{out}(s,t) = k_{out}s$, the general theory simplifies to the known kinetic equation $d\Phi/dt = J(t) - (k_d + k_{out})\Phi$ (Lauffenburger and Linderman, 1993; Klausner *et al.*, 1985; Tzafirri *et al.*, 2004). However, nontrivial system behavior including delayed forwarding of spikes of cargo or signals can only be accounted for by eqn. [5] which again requires to solve eqn. [1].

Implications for Cargo Sorting

Besides describing degradative cargo trafficking, this theory is also applicable to recycling cargo and membrane turnover itself. The heterotypic fission process (Figure 2(e)) will then play the essential role. Both, homotypic fusion and heterotypic fission of membrane are tightly coupled as shall be pointed out at the end of this section. For arbitrary but qualitatively similar shapes of EEs before and after a fusion event, the volume grows as the third power of a linear dimension whereas the membrane area only grows with the second power leaving excess membrane that can be extracted through membrane tube formation and then be recycled toward the plasma membrane (Skjeldal *et al.*, 2012). The membrane tube separation from a post-fusion EE also facilitates the recycling of receptors and membrane-associated cargo. Cargo that is destined for accumulation and subsequent degradation (e.g., LDL) can be passively sorted from other cargo that is destined for recycling by separating the former cargo from the membrane. For instance, cargo taken up by receptor-mediated endocytosis can dissociate from its receptor upon the pH decrease in EEs compared to the extracellular space. A membrane tube has a particularly low volume to surface ratio and correspondingly little degradative cargo will leak into the recycling pathway. This passive sorting process without the need for receptors specifically localized to the bulk part of an EE is termed geometric sorting (Maxfield and McGraw, 2004). Geometric sorting reaches high fidelity through multiple iterations of fusion and fission among subpopulations (e.g., first among EEs and subsequently among recycling endosomes).

Conclusion

Characteristic macroscopic properties of the endosomal network as a whole emerge from the many stochastic endosome interactions on the microscopic scale. One such macroscopic property of interest is the probability of finding a large concentrated cargo packet versus many small cargo packets within a cell. The underlying endosome interactions have been difficult to investigate due to their highly parallel and stochastic occurrence. Here, a unifying theory has been presented which links the microscopic properties of endosome interactions to the emergent macroscopic properties of cargo trafficking in the

endosomal network. The theory allows to infer microscopic kinetic parameters such as the fusion rate between endosomes from the statistics of the whole endosomal network at fixed time points after cargo internalization, lending this approach to *in vivo* studies that require fixing of samples. The results are robust and sensitive because the cargo statistics average over many stochastic events in many cells.

Transcription Factor Networks

Introduction

The animal body is a complex system which is regulated by a series of interconnecting networks set up during the initial stages of development. These large transcription factor networks, or gene regulatory networks (GRNs), are composed of sets of smaller networks, or modules, responsible for specific subroutines in the patterning process. For example, in the fruit fly, *Drosophila melanogaster*, two cascading GRNs serve to pattern the axes of the embryo setting up gene expression domains in the adult fly (Reeves and Stathopoulos, 2009; Perkins *et al.*, 2006; Jaeger *et al.*, 2004). Different networks are responsible for correct differentiation later in development. As an example, the GRN map for the dorsal–ventral axis is described in Figure 1. This network features many interactions between different transcription factors to properly pattern the major tissues along this axis in the developing embryo.

The final results of these networks can be seen in the correct differentiation of organisms ranging from fruit flies to sea urchins to humans. While these organisms may seem varied, each uses multiple GRNs consisting of similar wiring strategies. At the mechanistic level, all GRNs are based on the same principles: transcription factors binding to specific DNA sequences and regulating proximate genes. These genes in-turn may code for transcription factors that regulate still other genes.

At a higher level of abstraction, collections of a handful of such genetic interactions may be overrepresented patterns of functional interactions called motifs. While the identity of the genes themselves differ, network motifs with the same wiring have roughly the same function, and make up the complex GRNs seen in all of these animals (Reeves and Stathopoulos, 2009; Milo *et al.*, 2002; Thieffry and Sanchez, 2003; Peter and Davidson, 2009a). Some common motifs are: repression, feedforward loops, positive feedback, negative feedback, and

Figure 1 GRN map of the system patterning the dorsal–ventral axis in the *D. melanogaster* early embryo from 2 to 5 h after fertilization. The activity of each transcription factor on the other members of the system is shown. The green, yellow, and blue boxes represent the three types of embryonic tissue. In addition to signaling within a specific tissue type, activity also occurs between tissues. Reprinted from Levine, M., Davidson, E., 2005. Gene regulatory networks for development. *Proceedings of the National Academy of Sciences of the United States of America* 102 (14), 4936–4942.

cross-repression. These motifs serve as building blocks, with each interaction serving a specific functional role in gene regulation. Together these basic interactions serve to create a properly patterned organism.

In addition to studying these components of GRNs, more can also be learned by understanding features of the networks as a whole. Global properties of GRNs, such as the small-world property, the scale-free property, and modularity, are responsible for many advantageous design features of GRNs. For example, the GRN depicted in Figure 1 is modular in that it is divided into parts that perform separate biological tasks (patterning the individual tissue systems). In this article, we will review the common properties of GRNs at each level of abstraction: local, intermediate (motifs), and global. Our focus is on GRNs acting in development, however many of the same features can be applied to other biological contexts, ranging from metabolism to homeostasis.

Local Properties of GRNs

At the most basic level, GRNs are composed of transcription factors specifically binding to DNA sequences to regulate nearby genes. Typically, gene regulation is depicted as occurring 5' to a gene's transcriptional start site, but these regulatory elements could be downstream of the gene, as well as within an intron of a gene, or even within a neighboring gene. *cis*-regulatory elements (i.e., the DNA sequences to which transcription factors bind) often contain clusters of several binding sites for distinct transcription factors that each converge to determine the transcriptional state of a gene (Figure 2 (a)). In this section, we'll discuss how these interactions are experimentally verified, and how they are modeled.

Constructing GRN Maps

To construct a GRN map, one must proceed at the local level, with the verification of direct interactions between transcription factor and the regulated gene (Peter and Davidson, 2009b). If an organism's genome is sequenced, part of this approach may include a computational search for known binding site sequences. However, a computational approach is rarely sufficient by itself, due to the fact that most binding sites are short, with significant ambiguity at several positions, making the frequency of purely sequence-based hits prohibitively high, with many false positives. Furthermore, as mentioned above, a gene may be regulated by *cis*-elements that may be a significant distance from the transcriptional start site.

Several lines of experimental evidence can be employed in verifying a gene regulatory interaction. Direct evidence of transcription factor binding is valuable. One way to find regions bound by transcription factors is ChIP (Chromatin Immunoprecipitation)-based experiments. However, while these data reveal bona-fide physical interactions, it is not always clear which of these interactions are functional, resulting in false positives.

Correlative evidence in gene expression provides a solid foundation for determining the veracity of a genetic interaction. It should be verified the transcription factor is present in the same set of cells as the effect (either transcription or

Figure 2 Local properties of transcriptional regulation. (a) Structure of *cis*-regulation. *cis*-Regulatory elements, represented by blue boxes, contain clusters of binding sites for several transcription factors (colored circles). These clusters can be close to, far from, or even downstream of the transcriptional start site (represented by arrow). (b) Example of gene, G, with two inputs, U1 and U2. (c) Regulation of G can be represented by Boolean logic. In this example, both inputs are necessary for gene expression. The logic is represented by an AND gate. (d) Cube representation of the eight possible states for the variables U1, U2, and G. Each vertex represents a state in which the variables are either 1 or 0 (inputs in blue, output in red). The only allowable states are indicated by red squares. (e) Continuous representation of gene expression output. The two inputs can vary continuously from zero to maximal, resulting in a continuous variation in G. Often, the input/output relationship is taken to be ultrasensitive, which approximates a logical on/off system. ((b)–(e)) Modified from Bolouri, H., Davidson, E.H., 2002. Modeling transcriptional regulatory networks. *Bioessays* 24 (12), 1118–1129. Copyright © 2002, Wiley periodicals, Inc. Used with permission.

repression of the target gene, depending on the character of the putative regulation). In a similar manner, perturbing transcription factor expression (through knockout mutation, ectopic expression, or RNA interference) should have the expected effect on gene expression.

Enhancer trap analysis, which tests the sufficiency of a stretch of DNA to control a gene expression pattern, is one of the most important tools for verifying the role of the DNA sequence in driving gene expression. In this method, the *cis*-regulatory element in question is cloned upstream of a minimal promoter and a marker gene (commonly bacterial *lacZ*, as this gene is not natively present in metazoans). If transgenic expression of this DNA cassette results in the expression of *lacZ* in the pattern of the endogenous gene from which the putative enhancer was derived, this is strong positive evidence the enhancer in question regulates gene expression. Further evidence for the action of a specific transcription factor on this enhancer would include mutating the transcription factor binding sites within the transgenic enhancer and monitoring the resulting change in *lacZ* expression.

In all, the identification of the regulatory interactions of a single gene can be laborious and time-consuming

(Yuh *et al.*, 2001). In this manner, developmental GRN maps, such as for the sea urchin endomesodermal network and the *Drosophila* dorsal–ventral and anterior–posterior patterning networks, have resulted from many years of painstaking experiments performed by a large number of scientists.

Modeling *cis*-Regulatory Interactions

Once a set of *cis*-regulatory interactions have been experimentally identified for a given gene, how should one predict the effect transcription factor expression has on transcriptional output? Often, these interactions are modeled using Boolean on/off logic (Bolouri and Davidson, 2002). From a digital point of view, gene regulation can be seen as a type of logic gate. For example, take a gene, *G*, regulated by two transcription factors, *U1* and *U2* (Figure 2(b)). If this gene requires both activators to be present in order to be activated, this is taken as an AND gate (Figure 2(c)). The presence (or absence) of the transcription factors sets *U1* or *U2* to a value of one (or zero), resulting in the output being either on or off (Figure 2(d)). Another common example is an OR gate, in which the presence of either transcription factor is sufficient for transcriptional activation. If there are competing inputs (if *U1* were an activator and *U2* a repressor), this could be modeled by logic such as ‘*U1* AND NOT *U2*.’

The digital approach has the advantage of needing to know only the wiring topology and logic of the network; binding affinities and other biophysical parameters are not needed. As such, it is a very coarse-grained approach. When the purely digital logic approach does not have sufficient detail, a continuous approach may be taken (Bolouri and Davidson, 2002). For example, in the case of a series of morphogen-mediated gene patterns, a concentration gradient (analog signal) of a protein is read-out by cells in the tissue to be patterned. In such cases, often the relationship between transcription factor(s) and transcriptional output may be modeled as a highly sigmoidal (ultrasensitive) function (Figure 2(e)). Such models seek only to capture the phenomenology of transcriptional regulation, and most of the biophysical interactions are grouped into a handful of parameters. If the response is sensitive enough, these models approach the switch-like digital case.

If more mechanistic detail is desired, thermodynamic approaches have also been employed, in which the probability of transcription is related to the equilibrium of transcription factor binding site occupancy (Lai *et al.*, 2004; Reeves *et al.*, 2006; Saha and Schaffer, 2006; Zinzen *et al.*, 2006). These models tend to be less switch-like, and require detailed knowledge of the binding affinities and interactions among transcription factors at the *cis*-regulatory locus. Each of these approaches (digital/topological, phenomenological, and mechanistic/thermodynamic) has advantages and should be employed based on the level of input detail known, the level of output detail desired, and computing power available.

Motifs

At an intermediate level of abstraction, the interactions among three or more genes can serve a basic functional purpose, regardless of the identity of the genes involved. These network

Figure 3 Some of the most common motifs including: repression (a), cross-repression (b), negative feedback (c), and positive feedback (d). (a) Repression motif, one protein (*X*) represses the expression of a second protein (*Y*), this can be seen in dorsal–ventral patterning in the *Drosophila* embryo between *Sna* and *Sog* (Stathopoulos and Levine, 2002; Maduro and Rothman, 2002). (b) The cross-repression motif features mutual inhibition between two proteins (*X* and *Y*) and occurs between *Hb*, *Kni*, *Gt*, and *Kr* in the anterior–posterior patterning system in the *Drosophila* embryo (Jaeger, 2011). (c) Negative feedback features one protein (*X*) activating a second protein (*Y*) where the second protein represses the expression or inhibits the function of the first protein; this motif is seen in the tumor regulatory pathway between *Mdm-2* and *p53* (Oren, 1999). (d) Positive feedback is similar to negative feedback except the second protein (*Y*) activates or facilitates the first protein (*X*); this can be seen in the vulval formation pathway in *C. elegans* where *LIN-12* activates *LAG-1*, which in turn activates *LIN-12* through activation of *mir-61* followed by repression of *vav-1*, which in turn represses *LIN-12*.

interactions, or motifs, do not often act as functionally separable from the rest of the network, yet nevertheless have well-defined kinetic behavior (Babu *et al.*, 2004). Several motifs have been discovered to be overrepresented sets of connections (Milo *et al.*, 2002), implying the functional sub-routines carried out by these motifs may have an important, general purpose in regulation of gene expression.

Some common motifs (Figure 3) are repression, cross-repression, negative feedback, positive feedback, and feedforward loops. These motifs may seem very different, and in fact can be used in very different ways; they all function to increase the ability of an organism to create reproducible patterns despite perturbations and obstacles to proper development. In each of these systems, transcription factors bind to other transcription factors or to *cis*-regulatory elements to activate or repress expression of other transcription factors. These interactions are seen throughout development in a variety of systems. Our understanding of how these interactions can be grouped into different motifs to produce a given result in one system can be applied more broadly to a similar group of interactions, or the same motif, in another system.

Repression

Perhaps the simplest motif found during development is repression. During patterning, morphogen gradients activate expression in large domains based on concentration thresholds. In many instances, expression domains must be restricted

to limited regions, which can be achieved through repression by a neighboring protein (Stathopoulos and Levine, 2002; Maduro and Rothman, 2002). For example, along the dorsal-ventral axis of the *Drosophila* embryo, Snail is expressed in a narrow domain at the ventral midline and represses *short gastrulation* (*sog*) (Stathopoulos and Levine, 2002). This repression by Snail eliminates *sog* expression in the ventral-most cells, where Snail is present, dividing *sog* expression into two broad lateral stripes (Stathopoulos and Levine, 2002). Just like in the *Drosophila* embryo, *Caenorhabditis elegans* need to control the spatial domain of gene expression in endoderm development (Maduro and Rothman, 2002). In this system, SKN-1 activates expression, whereas POP-1 represses expression, creating a switch that serves to direct tissue to either an endoderm or mesoderm fate, thereby limiting the boundaries of the mesoderm (Maduro and Rothman, 2002). Similar regulation occurs in patterning the *Drosophila* egg and heart just to name a few of the diverse uses for repression (Cripps and Olson, 2002; Wasserman and Freeman, 1998). In each of these instances an input signal activates expression over a large region, and repression is used to eliminate this expression in certain region or after a certain period of time.

Cross-repression

Mutual inhibition, or cross repression, can be used to produce stripes or clear borders between gene expression regions in many different organisms. In the developing *Drosophila* embryo, one of the first steps to patterning of the anterior-posterior axis is the proper positioning of the so-called gap genes, namely Knirps, Hunchback, Giant, and Krüppel (Jaeger, 2011). The initial expression of these gap genes are established by the morphogen Bicoid in large overlapping domains (Jaeger, 2011). Cross repression between neighboring genes refines these domains and creates sharp borders between the domains (Jaeger, 2011). Since each region of transcription factor inhibits the neighboring transcription factor, two stable regions of expression are produced, which easily respond to perturbations near the interface of expression (Jagla et al., 2002). Similar cross repression activity occurs in the specification of cardiac and muscle cell fates in the *Drosophila* embryo (Jagla et al., 2002). These sharp domain borders are needed to create clear limits on downstream gene expression and therefore delineate positioning of tissue differentiation.

Mutual inhibition also regulates the branching of cells in mammalian lungs, mammary epithelial cells, trachea in flies, and vasculature in flies (Lu and Werb, 2008). In the fly trachea, mutual inhibition regulates the number of branches by determining the leading cell through competition for branch-inducing factors (Lu and Werb, 2008). Similarly, in mammary epithelial cells, mutual inhibition functions as a mechanism for cells to recognize surrounding cells and avoid other branches; this results in new branches turning away from the current line of growth and branches to end as they approach another branch (Lu and Werb, 2008). The use of mutual inhibition by branching cells functions similarly to the earlier examples of defining borders of stripes of gene expression in the developing embryo. In these diverse systems, mutual inhibition or cross repression provides a method for cells to recognize neighboring cells and to stabilize the interactions

between these cells by controlling the position and number of branches in a tissue or by controlling the downstream signal a region will receive prior to tissue differentiation.

Negative Feedback

Negative feedback can be used to buffer a system against perturbations, therefore making it more robust (Ma et al., 2009). In mice, a negative feedback loop featuring Mdm-2 regulates the degradation of p53, a tumor suppressor gene (Oren, 1999). In this loop, p53 binds to the *mdm-2* gene, stimulating the production of Mdm-2 protein, which then binds to p53 to inactivate and stimulate p53 degradation (Oren, 1999). The result of this contradictory relationship is a tight control over p53 expression, which is important since improper control of p53 can result in cancer (Oren, 1999). A similar negative feedback loop exists in embryonic stem cells to control pluripotency and self-renewal (Pan et al., 2006). In these systems negative feedback serves to limit gene expression thereby adding a level of control to the system; the importance of this control is apparent in the prevention of cancer, but is also important in a number of different systems.

Alternatively, oscillations can also be produced using negative feedback. Oscillations result in periodic expression of genes in time or space. This can serve as a method to produce evenly spaced stripes in a field as the tissue is created from replicating cells. During vertebrate somitogenesis, multiple negative feedback loops produce oscillations in Fgf, Wnt, and Notch which control the segmentation clock mechanism (Aulehla and Herrmann, 2004; Gibb et al., 2010). This creates periodic gene expression, which results in each segment forming at specific time intervals and therefore in specific positions in the tissue (Aulehla and Herrmann, 2004; Gibb et al., 2010). This oscillatory behavior is especially important in tissue that experiences directional development, creating stripes of expression as the tissue is created. In addition oscillations can also be used to provide a signal between pathways, eliminating problematic cross-talk. This occurs through negative feedback between NF κ B and I κ B in mammalian cells which produced oscillations in the translocation of NF κ B (Nelson et al., 2004; Lo et al., 2009). This produces an analog to digital signal to encode cell fate based on the frequency of oscillations rather than the amplitude of the signal (Nelson et al., 2004; Lo et al., 2009).

In some instances it can be desirable to limit the length of time or range of a signal; this effect can also be accomplished using negative feedback. In this case when a threshold is reached the signal can be turned off using a negative regulator; this type of regulation occurs in the JAK/STAT pathway (Janus kinase/signal transducers and activators of transcription) in vertebrates (Rawlings et al., 2004). This provides a valuable method to control signaling by turning off expression as a new stage in development is reached, it can also be used in regulation of tissue to turn-off a signal after the perturbation to the system has been removed.

Negative feedback can be used to achieve multiple objectives. Most notably is to buffer the system against perturbations by interlocking the expression of two genes and thereby preventing fluctuations from being carried over into downstream gene expression. To create properly patterning tissues, negative

feedback, through oscillations, can create reproducible bands of gene expression. These are just a few of the many ways negative feedback is used to produce properly differentiated tissues.

Positive Feedback

Positive feedback can also provide robustness to perturbations to the system. This robustness does not sacrifice sensitivity to the input signal (Hornung and Barkai, 2008; Kadelka *et al.*, 2013). In many systems switch-like behavior is used to achieve this robustness and produce precise borders, by creating bistable systems (Shah and Sarkar, 2011; Siegal-Gaskins *et al.*, 2011; Graham *et al.*, 2010). In bistable systems two equilibrium states can be achieved, with a small perturbation, the system will settle into a different state. This can be seen in endomesoderm specification in sea urchins (Minokawa *et al.*, 2005; Yuh *et al.*, 2004). In this system, initial β -catenin activates *wnt8* and *blimp1/krox* expression; this in turn causes nuclearization of β -catenin and therefore more *wnt8* and *blimp1/krox* to be expressed (Minokawa *et al.*, 2005). In this case, relatively low levels of β -catenin are needed to create a stable domain of Wnt8 expression (Minokawa *et al.*, 2005). Positive feedback is used to create bistable systems in other systems such as the mouse hindbrain, *Drosophila* wing, and *Xenopus* oocyte (Barrow *et al.*, 2000; Nonchev *et al.*, 1996a,b; Vesque *et al.*, 1996; Yan *et al.*, 2009; Xiong and Ferrell, 2003).

In a variety of organisms, similar systems exist where positive feedback produces precise regions of expression following an input signal. This can be seen, for instance in the control of vulval formation in *C. elegans* development (Yoo and Greenwald, 2005). In this system LIN-12 activates LAG-1 expression which goes on to activate mir-61 expression (Yoo and Greenwald, 2005). In turn, mir-61 represses *vav-1* which is a repressor of *lin-12* (Yoo and Greenwald, 2005). While varying in construction, positive feedback loops occur in many different systems in nature, including *C. elegans* neuron differentiation, *Drosophila* gut patterning, *Drosophila* eye development, and the interferon pathway in animal immune response (Johnston *et al.*, 2005; Bienz and Tremml, 1988; Johnston *et al.*, 2011; Taniguchi and Takaoka, 2001). In each of these cases positive feedback is able to use relatively small initial signals to effectively pattern tissue from stable domains of gene expression.

Feedforward Loops

Feedforward loops can help a system to respond to perturbations. Feedforward loops come in two flavors: coherent and incoherent. For coherent feedforward loops, the direct effect gene X has on gene Z is the same as the effect of gene X on gene Z indirectly through gene Y, as shown in Figure 4. With incoherent feedforward loops, it is the opposite. Incoherent feedforward loops can be very useful to reset a system after it responds to a perturbation (Ma *et al.*, 2009). These incoherent feedforward loops are found to regulate multiple systems in yeast and *Escherichia coli* (Milo *et al.*, 2002; Shen-Orr *et al.*, 2002).

Incoherent feedforward loops can also be used to produce stripes in many different systems including the *Drosophila*

Figure 4 Feedforward loops can take the form of either coherent (a) or incoherent (b). In a coherent feedforward loop, the direct effect gene X has on gene Z is the same as the effect of gene X on gene Z indirectly through gene Y. This can be accomplished in a simple loop where X activates Y and Z, and Y goes on to activate Z (a). However in the incoherent feedforward loop, the effect gene X has on gene Z indirectly through gene Y is opposite the effect it has on gene Z directly. This can be accomplished by altering the network such that X represses Y (b). (c) An incoherent feedforward loop regulates decapentaplegic regulation of Wingless in the *Drosophila* notum.

notum and *Drosophila* eggshell (Hironaka *et al.*, 2012; Yakoby *et al.*, 2008). The feedforward loop allows for gene expression far from the source of the activation signal, at low morphogen levels (Hironaka *et al.*, 2012). In the *Drosophila* notum, the morphogen Decapentaplegic (Dpp) activates Pannier (Pnr) and U-shaped (Ush) production (Hironaka *et al.*, 2012). Pnr and Ush can form a complex to repress *wingless* (*wg*) expression or unbound Pnr can activate *wg* expression (Hironaka *et al.*, 2012). Together these two paths combine to form a stripe of Wg at low levels of Dpp (Hironaka *et al.*, 2012). In each of these cases, the feedforward loop allows for gene expression at low levels of the input signal at the periphery of the differentiating field.

In some instances an initial signal is only available at the start of development. In these cases it is desirable to amplify this signal and provide a sustained signal output. This effective signal duration can be achieved using a feedforward loop. In patterning the dorsal–ventral axis of the developing *Drosophila* embryo, a combination of coherent and incoherent feedforward loops signal from Dorsal through either Snail or Twist to control expression of multiple genes in the neurogenic ectoderm (Zartman and Shvartsman, 2007). In each of these cases the feedforward signal is used because it creates a mechanism to utilize a small input signal and transform it.

Global Properties of GRNs

The global properties exhibited by GRNs are largely dictated by the topology of the wiring of the network. Studies of the global properties of GRNs have often visualized GRNs as ‘directed graphs,’ with genes being the nodes, and regulation of one gene on another being a directed connection. By and large, GRNs have been found to adhere to several general topological features, meaning that GRNs studied to date display many common properties. In this section, we will review three global topological features – the small-world property, the scale-free property, and modularity – and discuss what each these features imply.

Small-World Networks

Many biological networks – including metabolic networks, neural networks, as well as GRNs – have been found to be of the ‘small-world’ character (Albert, 2005). Several types of human networks also exhibit this property, such as social networks, power grids, and connections among actors in Hollywood films (Watts and Strogatz, 1998b). Small-world networks are ones in which any two nodes are connected by a relatively short series of paths, yet the probability of any two given nodes being directly connected to each other is relatively high. In other words, small-world networks achieve a balance between maintaining a low degree of separation (commonly referred to as ‘six degrees’ of separation) and having a high degree of clustering (or ‘cliquishness’).

In contrast to small-world networks, one may have a completely regular network, or lattice network, in which all nodes are connected only to their ℓ nearest neighbors. This network has a high degree of clustering, but to move from one node to another on the other side of the network requires many local steps. One simple way to construct a small-world network is to begin with a lattice network, and make a few ‘short circuit’ connections across the network (Watts and Strogatz, 1998b; see Figures 5(a) and 5(b)).

On the other hand, one may have a completely random network, where the probability of two nodes being directly connected is uniform across all nodes. In such a network, the idea of clustering is completely lost, yet the shortest distance between any two nodes is small, allowing one to cross from one node to another in a relatively small number of steps.

Small-world networks have the advantage of keeping both qualities of local clustering and global connectivity. This allows for rapid propagation of information among all nodes in the network, yet also allows for groups of nodes to act together in a similar, local task.

Scale-Free Networks

Besides focusing on the paths and connections between nodes, another way to characterize a network is to focus on how many connections each node has. Early network studies assumed the number of node connections conformed to a Poisson distribution, and thus was strongly peaked at an average value $\langle k \rangle$. This implied that the number of nodes with more than $\langle k \rangle$ connections decayed exponentially and that there were few if any nodes with many more than $\langle k \rangle$ connections. In that sense, the ‘scale’ of the network was $\langle k \rangle$ connections per node.

However, as storage and computing power increased, and topological data of large networks became more available, it was understood that few if any naturally occurring or man-made networks followed a Poisson distribution in node connectivity. Instead, the probability that a node has k connections decays as a power law. $P(k) \propto k^{-n}$ (Barabasi et al., 1999). This result implied that there were a comparatively large number of nodes with higher-than-average connectivity. In this sense, there was no strongly preferred number of node connections, and thus such networks have been dubbed ‘scale-free’ (Barabasi et al., 1999).

Intuitively, a scale-free network is one in which most nodes are connected, on average, to a small number of other nodes.

However, there are a small but significant number of nodes that are highly connected (see Figure 5(c)). These ‘hubs’ hold most of the network together, and at a higher level of connectivity, there are still larger hubs that connect the smaller hubs together. In this sense, the scale-free property has much overlap with the small-world property, but they are not identical. For example, both types of networks display a relatively low degree of separation. In scale-free networks, this property is provided by hubs, or master regulators, that connect parts of the network together, whereas in small-world networks, this property could be achieved simply by making a few random connections across the network (Watts and Strogatz, 1998b; Barabasi et al., 1999). On the other hand, a necessary component of a small-world network is local clustering, yet this property is not required to be a scale-free network. For example, compare the two scale-free networks in Figures 5(c) and 5(d).

As with the small-world property, there is a long list of both man-made and biological networks that exhibit the scale-free property, including GRNs. The scale-free property is advantageous for these networks, as it imparts a high degree of fault- and failure-tolerance (Albert et al., 2000; Jeong et al., 2000). This is because if a gene is randomly disabled by mutation, it is likely to have been a peripheral gene rather than a highly connected hub. On the other hand, even mutations to single hubs can sometimes be tolerated, due to the connectedness of the network through the rest of the hubs. This property is also advantageous from a medical perspective. For example, if several hubs can be intelligently targeted, such as in cancer therapy, it is possible to completely destroy network operation. None of this is to say that mutating a single essential gene, whether peripheral or highly connected, will not have disastrous consequences; indeed, that is the natural consequence of the fact that genes have important functions in the cell. Instead, the point is a scale-free network is designed in such a way as to avoid cascading failures, from the network point of view.

Modularity

As we have discussed before, sets of interactions between a handful of genes are typically characterized as ‘motifs,’ and the topology of the motif determines its kinetic behavior. At a higher level of abstraction, several motifs combine together to form systems of motifs called modules. The modularity of GRNs means that small ‘communities’ of genes have a high level of interconnectedness and together perform a related function, such as cellular differentiation. These modules are further connected (sparsely) to each other to compose the entire GRN.

It is clear that the modularity of a GRN is related to the scale-free property, as the hubs in a scale-free sense serve as master regulators connecting several modules. However, these properties are not identical. It is possible to have a scale-free network in which local clustering is not maintained, resulting in a non-modular (and non-small-world) network (Figure 5(c)). Even in scale-free networks with high degrees of clustering, it may be difficult to identify separate modules if there is a significant degree of cross-connectivity among groups (Figure 5(d)). Modular networks may also violate the

Figure 5 Illustrations of the small-world, scale-free, and modular properties of a network. (a) Lattice network. Each node is connected to its nearest and next-nearest neighbors. (b) Small-world network, made from randomly rewiring three connections in the lattice network. Because the vast majority of nodes have four connections, this is not a scale-free network. (c) Scale-free network. Most nodes have very few connections, but there are a significant number of nodes with many connections. However, this scale-free network was randomly wired, so has very low clustering, and thus is not small-world. Node color code: From dark red (most connections), through red, orange, yellow, green, blue, and finally to dark blue (fewest connections). (d) Scale-free and small-world network. Connections in this network were made preferentially so that clustering is high (a node's neighbors will also likely be connected to each other). However, cross-connections between local groups are too high for this network to be considered modular. Color code same as in (c). (e) Modular, lattice network. Each open circle at the end of a spoke represents a lattice network as in (a). The regular lattice structure rules out this network from being small-world or scale-free, even though it is modular. (f) Small-world, scale-free, modular network. Clustered groups of nodes can be grouped into modules (light green, light orange, and light purple) that have relatively few connections between them. Color code is same as in (c). (a) and (b) adapted from Watts, D.J., Strogatz, S.H., 1998a. Collective dynamics of 'small-world' networks. *Nature* 393 (6684), 440–442. Macmillan Publishers Ltd. Copyright © 1998. Used with permission.

small-world property. The network in [Figure 5\(e\)](#) is modular, but is neither scale-free nor small-world. In contrast, the network depicted in [Figure 5\(f\)](#) is a good example of a scale-free, small-world, modular network: each highlighted group of nodes is tightly clustered, largely separate from the others, and is centered on a few highly connected hubs, yet there are

enough connections among the modules to preserve a low degree of separation.

It is also important to note the modularity of a network depends not only on its connectivity, but also on the specific function of the genes in the local cluster. Local clusters of genes must act together in a specific function for a network to

be considered modular. For example, in sea urchin development, there are distinct modules, composed of groups of interacting genes, that separately control endoderm, mesoderm, and ectoderm development (Peter and Davidson, 2009b). It is evident that genes within a developmental module must be co-expressed in a subset of cells at a particular stage of development.

In the realm of human-designed systems, building objects with modularity is a well-established engineering principle. As such, the modularity of GRNs reveals an analogy to engineered systems. For example, human engineers design hardware (or software) subsystems, with self-contained purposes, that can be 'swapped out' for different applications, such as the modular bay on a laptop, which can be used for an optical drive, an extra hard drive, or an extra battery, among other uses. Thus, for GRNs, modularity provides adaptability, in which a subset of the GRN can be slightly modified without largely affecting the rest of the network. As a side benefit, the modularity of GRNs allows for more facile study by curious scientists.

Conclusions

During development organisms utilize networks of interacting genes, known as GRNs, to properly pattern the organism. Several different properties can be used to describe the overall construction of these GRNs, such as being modular, scale-free, and small-world. In addition to looking at these GRNs as a whole, more can be learned about these networks by looking at the smaller functional elements, known as motifs, which make up these GRNs. These motifs accomplish a diverse range of specific objectives within the larger system. These objectives include: responding to perturbations, amplifying a short-term signal, creating sharp borders between expression regions, and producing oscillations. These differing objectives can be accomplished using motifs such as repression, cross-repression negative feedback, positive feedback, and feedforward loops. In addition to being used for multiple objectives, the same motifs are used by many different systems and occur frequently throughout nature to pattern tissues in many different organisms. Because of this, the information learned about these motifs in one organism can be applied to the study of other organisms as well. This ability to apply knowledge across organisms provides a valuable tool in understanding gene regulation in general as well as in a particular organism of interest.

Introduction

It is becoming increasingly clear that normal functioning of biological cells involves careful coordination of a range of processes acting across diverse spatial and temporal scales (Meier-Schellersheim *et al.*, 2009; Walpole *et al.*, 2013): essential cellular functions such as macromolecule synthesis and degradation, metabolism, proliferation, and death must be tightly regulated. Aberrant regulation of these processes caused, for example, by mutations in a specific gene may alter a cellular phenotype and, ultimately, become manifest at the tissue scale as a disease such as cancer or diabetes (Goncalves *et al.*, 2013). The complex nonlinear feedbacks that regulate such processes cannot typically be understood by deductive or linear thinking alone. Mathematical and computational modeling represents a logical framework within which to understand such complex systems. Modeling involves the creation of an abstract representation of a biological system, often using the language of mathematics or computer science. Model simulations provide a method for predicting how the biological system of interest will behave when subjected to specific conditions. Traditionally, such models have focused on a single time and/or space scale. The growing realization that many biological systems involve processes that occur on different space and timescales is now creating a strong demand for new, multiscale models that integrate phenomena acting on different levels of organization: the spatial scales may range from the molecular to the tissue while the temporal scales may range from those associated with molecular vibrations to the lifespan of a cell. Such multiscale models have the potential to increase our understanding of complex biological systems in a qualitative and quantitative manner and simultaneously to bridge the gap in understanding between *in vitro* and *in vivo* experiments (Walpole *et al.*, 2013).

This article serves as an introduction to the section on vertical integration that follows and is organized as follows. We start by introducing the spatial and timescales of biological resolution that can be modeled and explain the different philosophies that underpin multiscale models. We then

describe briefly the mathematical and computational techniques and related software that can be used to construct and simulate multiscale models. After presenting a couple of case studies, the article concludes with a discussion of the challenges and opportunities associated with vertical integration.

Before continuing, however, we pause to explain what we understand by vertical integration and how it differs from systems biology.

- What is vertical integration?

Vertical integration is the merging together of mathematical and computational models formulated at different spatial and/or temporal scales to produce multiscale models of a biological process.

- What is the difference between vertical integration and systems biology?

Both vertical integration and systems biology aim to increase understanding of complex biological systems through the development and investigation of mathematical and computational models. The key difference is that vertical integration must involve the coupling of models that act at different spatial and/or timescales, whereas systems biology may focus on processes that act on one or more spatial and/or temporal timescales. In this respect, vertical integration can be viewed as a special case of systems biology.

The Multiple Time and Spatial Scales Associated with Cellular Biology

The range of space and timescales that can be integrated in cellular systems is vast. Consider, for example, the timescales associated with molecular vibrations (10^{-15} s), signal transduction (10^{-9} s), ligand binding (10^{-3} s), protein diffusion across a cell (1 s), and the doubling time of a tumor cell (10^5 s). The lengthscales of interest also span several orders of

Figure 1 A schematic diagram illustrating the different biological scales associated with multiscale modeling, together with the associated modeling approaches and experimental techniques. IP, immuno-precipitation; ODE, ordinary differential equation; PDE, partial differential equation; SPR, surface plasmon resonance; Y2H, yeast two-hybrid. Wiley Interdisciplinary Reviews: Systems Biology and Medicine 1 (1), 4–14.

magnitude, ranging from 10^{-9} m for proteins and 10^{-6} m for mitochondria, to 10^{-5} m for mammalian cell diameters and 10^{-2} m (or larger) for organs (see Figure 1 for details). A significant challenge associated with vertical integration is developing theoretical and numerical methods that can accurately and efficiently simulate processes which act on, and interact across, such diverse scales.

Approaches for Linking Scales in Multiscale Models: 'Top-Down', 'Bottom-Up,' and 'Middle-Out'

When constructing a multiscale model, typically only a subset of the space and timescales mentioned above are included. For example, a multiscale model of carcinogenesis (the initiation of a cancer due to a genetic mutation) might integrate genetic, proteomic, subcellular, and cellular processes, whereas a multiscale model of tumor invasion might focus on subcellular, cellular, and tissue scale phenomena. In other applications it may be natural to merge two scales or to decompose one scale into two or more components. As a rule, when formulating a multiscale model one

should be guided by the details of the system of interest rather than to follow a rigid and predefined framework (Southern *et al.*, 2008).

A related question that must be addressed when formulating a multiscale model is how to attribute causality. There are three main approaches: 'top-down,' 'bottom-up,' and 'middle-out' (Kohl *et al.*, 2010). The 'top-down' or classical physiological approach aims to explain observations at a particular scale in terms of mechanisms that occur on smaller, more fundamental scales, by including more and more detail as it becomes available. By contrast, the 'bottom-up' or molecular biology approach starts at a fundamental level (e.g., with a description of genes and genetic relationships) and aims to coarse-grain or average processes acting at a given scale to predict emergent or collective behavior at a higher, less detailed scale. In practice, feedbacks may operate across the scales, in which case a 'middle-out' approach that combines both top-down and bottom-up approaches may be more appropriate (Kohl *et al.*, 2010). Middle-out models typically start at a scale for which there is sufficient information to develop a mechanistic model. The model can then be extended by moving up or down the scales.

Mathematical and Computational Representations of the Components of a Multiscale Model

Once the scales of interest and an appropriate approach (e.g., top-down, bottom-up, or middle-out) have been identified, the next issue is to decide what mathematical and/or computational formalism is appropriate at each scale and for each process being modeled. While it is not possible exhaustively to list the options available, we illustrate below the sorts of choices that have to be made and refer the interested reader to [Southern et al. \(2008\)](#) and references therein for further details:

- Deterministic or stochastic (Is there a degree of randomness in the system that allows multiple solutions to be generated from the same initial conditions?)
- Discrete or continuous (Is the solution space decomposed into a finite number of discrete space or time intervals?)
- Dynamic or static (Does a variable evolve over time?)
- Spatially averaged or spatially resolved (Do the physical variables vary with position?)

The type of data available for model validation may guide the selection of modeling approaches. Thus, if quantitative and dynamic data is available for average protein levels within a population of cells, then a deterministic framework that is continuous in time and neglects spatial effects may be appropriate and a description of the associated signaling pathway formulated using systems of time-dependent ordinary differential equations (ODEs) and by appealing to the law of mass action to represent the chemical reactions. If only binary information is available about whether a protein is present or absent at a particular time, then a simpler, binary Boolean model, formulated using deterministic or stochastic logic rules, may be appropriate. In addition to ODEs and Boolean models, other modeling approaches that are used to develop components of multiscale models include partial differential equations (PDEs), stochastic differential equations, and agent based models.

PDEs, particularly reaction-diffusion equations, are widely used to model the continuous in time and space distribution of extracellular nutrients such as oxygen and glucose, waste products, drugs, hormones, and growth factors. Such models typically account for tissue scale processes such as diffusive and advective transport and local rates of production and consumption of the species of interest. Other processes that may be relevant at the tissue scale include biomechanical forces, electrical, and magnetic fields. Continuum models describing these fields are well-established. For example, in heart modeling, the bidomain and monodomain models are typically used to study defibrillation ([Keener and Sneyd, 1998](#); [Plonsey, 1988](#)). The bidomain equations comprise a pair of nonlinear PDEs that account for anisotropy in the electrical conductivity of the intracellular and extracellular spaces in cardiac tissue: they reduce to the monodomain equations when the electrical conductivity is assumed to be isotropic (i.e., spatially uniform) in both the extracellular and intracellular spaces. In separate work, [Owen et al. \(2011\)](#) incorporated a model for an externally applied magnetic field into an existing multiscale model of vascular tumor growth in order to investigate the potential for loading genetically engineered macrophages with magnetic

nanoparticles in order to enhance the delivery of cytotoxic drugs to hypoxic tumor regions. The above examples, in which different physical processes (e.g., forces, electrical magnetic fields) are considered, may be termed multiphysics models: they are a common feature of multiscale models.

PDEs, or stochastic differential equations, may also be used (in place of ODEs) to investigate processes that act on smaller spatial scales. For example, [Basan et al. \(2010\)](#) use PDEs to study the spatial variation in cytoplasmic levels of proteins associated with the Wnt signaling pathway while [Mazemondet et al. \(2012\)](#) formulated an alternative, stochastic model of the same pathway.

At the intermediate, cellular scale, a variety of discrete modeling approaches can be used to describe individual cells and their interactions ([Anderson et al., 2007](#)). These range from simple cellular automata, where each cell is represented by a single site on a regular lattice and predefined rules are used to update the state or phenotype of each cell ([Anderson et al., 2007](#); [Perfahl et al., 2011](#); [Youssef et al., 2007](#)), to more detailed and physically based models which account for cell mechanics ([Buske et al., 2011](#); [Galle et al., 2005](#)). While lattice-based models such as cellular automata and the Cellular Potts Model (CPM) ([Chen et al., 2007](#)) provide simple descriptions of the dynamics of cell populations, many of the associated model parameters are difficult to relate to experimentally measurable quantities. If mechanical effects and/or details of cell size and morphology are important, a less restrictive, off-lattice approach may be preferred. Off-lattice approaches include cell-center models in which each cell is represented by a single point and an associated surface area (or volume) which may be defined through a Voronoi tessellation ([Osborne et al., 2010](#)). Vertex models are an alternative off-lattice approach in which each cell is represented by a polygon (or polyhedron) whose vertices may be shared with neighboring cells ([Harvey et al., 2015](#); [Osborne et al., 2010](#); [Pitt-Francis et al., 2009](#)).

Assembling Multiscale Modeling

As stated above, multiscale models link models of biophysical processes that act at two or more different space and time-scales. They are typically constructed on a case-by-case basis, with different groups taking different approaches, even when studying the same system. Consider, for example, the wealth of multiscale models for diffusion-limited growth of avascular clusters of tumor cells suspended in culture medium. The models typically span three spatial scales, coupling subcellular, cellular, and tissue scale phenomena ([Anderson et al., 2007](#)) and are constructed in a similar, middle-out manner. Thus, at the tissue scale, reaction-diffusion equations describe the diffusion, natural decay, and consumption by the tumor cells of vital nutrients, such as oxygen and glucose, present in the culture medium. The local nutrient environment influences the subcellular dynamics: where nutrient levels are high, cells progress through the cell cycle; where nutrient levels are low they first exit the cell cycle and become quiescent and, then, if nutrient levels remain excessively low for a sustained period of time, the cells undergo necrosis and die. Behavior at the cell scale is coupled to the subcellular scale. On each timestep, each cell checks whether it has completed its cell cycle: if so, then it attempts to divide into two cells (the rules for cell

division are specific to the cell-based model being used). If the region surrounding the dividing cell is fully occupied by other cells (and/or the dividing cell is unable to push its neighboring cells away), then the cell may be contact-inhibited and division will not occur. Equally, the subcellular dynamics may dictate that the cell is removed from the system due, for example, to necrosis, the way in which this is achieved again being specific to the cell-based model being used. While sharing the above, generic attributes, the multiscale models of avascular tumor growth differ in two main ways: in the level of detail used to model subcellular phenomena (e.g., the cell cycle, metabolism, response to oxygen) and the framework used to model individual cells (e.g., cellular automata, vertex-based or cell-centered models). Despite these differences, many models of avascular tumor spheroids reproduce the same qualitative dynamics. Initially all cells are nutrient-rich and proliferate rapidly, causing the cluster to grow exponentially until cells toward the spheroid center become starved of nutrients, stop proliferating, and, if nutrient levels become sufficiently low, undergo necrosis. These changes cause the tumor's growth rate to transition from exponential to linear and eventually to plateau when the proliferation rate of nutrient-rich cells at the spheroid periphery balances the death rate of nutrient-starved cells at its center. Without access to the software used to generate the different models, it is difficult to understand what features of a particular multiscale model, and/or the computational algorithm used for its solution, are responsible for the observed dynamics. The open-source software CHASTE (see Section Relevant Websites) was designed, in part, to address questions of this type. CHASTE is a general purpose package that can be used to simulate multiscale and multiphysics models in biology and physiology (Pitt-Francis *et al.*, 2009). Due to its modular structure, different models of the same process can be used interchangeably and, thereby, CHASTE facilitates comparison of different multiscale models. For example, Osborne *et al.* (2010) used CHASTE to perform a systematic comparison of three multiscale models of homeostasis in the intestinal crypt, the models differing only in the approach used to describe individual cells. Extensive numerical simulations revealed that cell-center and vertex-based models of sheets of epithelial cells produce near identical results which differ markedly from those obtained when an alternative, fixed lattice, cellular-automation model was used.

While the existence of multiple multiscale models of the same physical system may seem unnecessary (in addition to multiple models of avascular tumor growth), there are also multiple multiscale models of vascular tumor growth and cardiac electrophysiology. In the long term, such diversity could prove beneficial. For example, in the same way as different models of weather forecasting are used to predict future weather patterns and different models of action potentials in the heart are now being used to predict patient responses to different cardiac drugs, the response of different multiscale models of avascular and/or vascular tumor growth to a particular chemotherapeutic drug (or radiotherapy) could be used to generate probabilistic predictions about the likely response of a particular tumor to a specific course of treatment.

A further advantage of having multiple multiscale models of the same system stems from the different predictions that they may generate. For example, in Alarcon *et al.* (2003) a

multiscale model of vascular tumor growth is proposed in which a network of blood vessels supply oxygen to a tissue containing normal and cancer cells. Numerical results are presented to show the way in which oxygen transport through the vasculature affects the morphology, size, and growth dynamics of the evolving tumor mass: the tumor expands as a radially symmetric mass if the oxygen tension is assumed to be distributed uniformly through the vascular network; its growth is heterogeneous and localized around oxygen-rich blood vessels when more detailed models that account for blood flow and hematocrit are employed. These qualitative differences highlight the importance of model validation in multiscale modeling, in this case they indicate that in order to generate realistic patterns of tumor spread it is important to model blood flow (and vascular adaptation) accurately.

While many aspects of composing and solving a multiscale model are problem-specific, there are several techniques and strategies that are widely applicable. It may be possible to exploit differences in space and timescales in order to make model simplifications. For example, since the kinetics of molecular binding and diffusion typically occur over short timescales, steady-state assumptions for their dynamics may be justified in the overall model architecture if one is concerned with longer timescales of hours, days, or weeks. Such reasoning and techniques have been widely used to model metabolic and signaling networks, the steady-state fluxes being used in a hierarchical manner to determine behavior at higher levels of organization (Quo *et al.*, 2011; Sun *et al.*, 2009).

Software for Multiscale Modeling

The diversity of theoretical approaches that may be used to model each component or submodel within a multiscale model (e.g., discrete or continuous, deterministic or stochastic, spatially averaged or spatially resolved), combined with the vast range of space and timescales that can be linked together, and the current limits on computing power, mean that it is unlikely that any single, multiscale modeling framework will ever be capable of simulating all possible multiscale systems. A survey of existing software for simulating multiscale models (the list of websites included at the end of this article provides links to this software) suggests that it is more likely that, in the future, generic software such as *compuCell3D* (see Section Relevant Websites; Chen *et al.*, 2007; Graner and Glazier, 1992) and CHASTE (see Section Relevant Websites; Pitt-Francis *et al.*, 2009) will be used to develop simple, prototype models for new applications while highly specialized software, which links only a limited number of space and timescales, will be used to generate detailed insight into specific systems, such as the heart and the model plant *Arabidopsis thaliana* (Band *et al.*, 2012; Kuchen *et al.*, 2012; Muraro *et al.*, 2014).

Since a central aspect of developing multiscale models is the integration of different simulation techniques and since software for many of these techniques already exist, it is natural to ask how existing software could (and should) be exploited for multiscale modeling. The *biomodels* database and *CellML* (see Section Relevant Websites) are two community-led initiatives designed to promote the reuse and integration of published models of biological systems. For example, the *biomodels*

database is a manually curated repository, containing hundreds of published models, represented using the systems biology markup language (SBML; see Section Relevant Websites). CellML is similar, but with a greater emphasis on model integration. Such endeavors highlight the need for agreed standards and ontologies for mathematical and computational models if the vision of multiscale modeling in biology and medicine, that is the seamless integration of models, simulation techniques, and experimental data, is to be realized (Meier-Schellersheim *et al.*, 2009; Wolkenhauer *et al.*, 2014).

Applications of Multiscale Modeling and Two Case Studies

While vertical integration is still in its infancy, there are a number of well-established multiscale models in the literature: of these the cardiac models of Noble, Hunter, and coworkers are arguably the most well-studied (Kohl and Noble, 2009). The articles that follow provide an excellent starting point for learning more about the state-of-the-art in multiscale modeling of angiogenesis, morphogenesis, neurogenesis, wound healing, inflammation, and cardiac modeling and also an overview of the computational approaches that are used to construct and simulate multiscale models. A common feature of these multiscale models is that they are multicellular and are designed to understand how subcellular processes (e.g., signaling networks), cellular processes (e.g., cell division, migration, and death) interact with tissue scale processes (e.g., the transport and consumption of growth factors,

nutrients and waste products). There is a complementary and distinct body of multiscale modeling focused exclusively at the subcellular scale. For example, hybrid multiscale models that combine quantum and classical mechanics have been proposed to study enzymatic reactions (Leach, 2001). Alternative hybrid models that couple stochastic and deterministic models for chemical reaction kinetics that operate over short, intermediate, and long timescales have also been developed and used to study the subcellular dynamics of the LacZ and LacY proteins in *Escherichia coli* (Burrage *et al.*, 2004). In separate work, Mashl *et al.* (2001) used hierarchical multiscale modeling to simulate the flux of potassium through a particular ion channel. Potential profiles for the passage of individual potassium ions through the ion channel were generated from molecular models and then used in molecular dynamics simulations to estimate the bulk diffusion coefficient of potassium ions in water. The diffusion coefficients were then included in Brownian dynamics simulations to establish how the flux of potassium ions varies with the transmembrane.

We present below two case studies which illustrate how multiple processes acting on multiple spatial, temporal, and functional scales may interact to generate homeostasis (in the intestinal crypt) or, alternatively, how they may contribute to disease progression (in diabetic retinopathy).

Case Study I: Homeostasis in the Intestinal Crypt

The intestinal epithelium is a rapidly renewing tissue, being completely replaced every 2–3 days in mice and 3–5 days in humans. In the large intestine, it comprises approximately

Figure 2 Homeostasis of the adult intestinal crypt. (a,b) Schematic representation and section of the crypt-villus unit in the mature small intestine. Proliferative cells reside in the crypts, while differentiated cells occupy the villus. Crypt progenitors migrate up (red arrow) the crypt-villus axis before shedding into the lumen. The process of epithelial renewal takes 3–6 days and is ensured by a small number of asymmetrically dividing stem cells at the bottom of the crypts. Wnt signaling in the adult intestine promotes proliferation of progenitor or transit-amplifying (TA) cells, as well as commitment toward secretory lineages. Wnt signaling may also drive terminal differentiation of certain secretory lineages. Although it is commonly believed that Wnt signaling may promote proliferation and/or differentiation of intestinal stem cells, there is no evidence that formally proves this (see arrows with question marks). In panel (a), black arrowheads indicate Ki67 positive TA cells, while white arrowheads indicate the Paneth cell compartment. Reproduced with permission from Gregorieff, A., Clevers, H., 2005. Wnt signalling in the intestinal epithelium: From endoderm to cancer. *Genes & Development* 19, 877–890.

2×10^7 crypts or test-tube-shaped invaginations. Stem cells located toward the base of each crypt proliferate occasionally, producing on average one stem cell and one semi-differentiated transit cell. Transit cells divide several times while migrating upwards before committing to either an absorptive or secretory fate. At the crypt orifice, mature cells undergo apoptosis and are shed into the intestinal lumen (Grossmann *et al.*, 2002; Yen and Wright, 2006). While the mechanisms by which cell proliferation, migration, differentiation, and apoptosis are regulated within the crypt remain fully to be elucidated, there is evidence that a spatial gradient in extracellular Wnt factors along the crypt axis determines the position-dependent rates of cell proliferation, differentiation, and death (and that cross talk with the delta-notch pathway drives cell-fate specification) (see Figure 2). A number of different multiscale models of the intestinal crypt have been developed and used to study processes such as monoclonal conversion

(Mirams *et al.*, 2012), cell-fate specification (Buske *et al.*, 2011), and early colorectal cancer (van Leeuwen *et al.*, 2009); for a review, see Kershaw *et al.* (2013), De Matteis *et al.* (2013).

Case Study II: Diabetic Retinopathy

At the subcellular scale, through its activation of protein kinase C (PKC)-delta and downstream phosphatases, chronic hyperglycemia causes dephosphorylation of platelet-derived growth factor (PDGF) receptors that normally promote the survival of pericytes, cells that envelop endothelial cells and, thereby, prevent fluid leakage from blood vessels and inhibit excessive endothelial cell proliferation. Dephosphorylation of PDGF receptors simulates pericyte apoptosis, leading to increased blood vessel permeability and uncoordinated endothelial cell proliferation throughout the retina. The cumulative effect of sustained periods of such microvascular hemorrhage and

Figure 3 Diabetic retinopathy as a case study in multiscale biology. A detailed look at how the pathogenesis of diabetic retinopathy is a function of multiple spatial scales across biology. Reproduced with permission from Walpole, J., Papin, J.A., Peirce, S.M., 2013. Multiscale computational models of complex biological systems. Annual Review of Biomedical Engineering 15, 137–154.

vascular remodeling is extensive tissue damage which, in its most advanced stage, can cause blindness due to retinal detachment at the macroscopic or tissue scale (see [Figure 3; Walpole et al., 2013](#)).

Challenges Associated with Multiscale Modeling

There are many theoretical, biological, and experimental challenges associated with simulating multiscale models. For example, how should deterministic and stochastic models be coupled? Should different coupling methods be used to couple across different space and timescales? Further, within a given multiscale model, how do numerical errors in the simulated values of deterministic variables (and, similarly, random variations in stochastic variables) propagate from one scale to another? Can different types of data that have been generated using different experimental techniques be integrated with multiscale models to generate biologically meaningful predictions? Are the parameter estimates associated with a particular submodel robust to changes in framework used to describe another component of the multiscale model? Interest in answering these open questions is currently driving much of the research in this field.

The equations governing the evolution of multiscale processes are often stiff since the range of length and space scales involved are large. While it is usually more efficient to use implicit numerical methods to solve stiff problems, for the large nonlinear systems generated by multiscale models, it can be unclear how to proceed: implicit methods may be prohibitively expensive to compute and explicit methods prone to numerical instability. In such cases, it may be appropriate to use semi-implicit methods, with some variables solved explicitly and others implicitly ([Southern et al., 2008](#)).

As already stated, multiscale models typically contain large numbers of variables and parameters. The development of fast, accurate, and reliable numerical methods for their simulation remains an active research area, with many groups reducing simulation times by exploiting parallel computing ([Chen et al., 2007](#); [Coveney and Fowler, 2005](#); [Harvey et al., 2015](#); [Youssef et al., 2007](#)). Such techniques are urgently needed if the full potential of multiscale modeling is to be realized: large numbers of simulations must be performed for model validation, parameter estimation, and also to generate experimentally testable predictions from the models. Since many of the parameters included in multiscale models are difficult or impossible to measure, parameter estimation remains an ongoing concern. Further, parameter values estimated from *in vitro* data may not be applicable for multiscale models describing *in vivo* systems. In such cases, techniques that permit rapid, systematic, and exhaustive searches of multidimensional parameter spaces are needed to identify physically realistic parameter values for multiscale models. Alternatively, improvements in *in vivo* imaging techniques may make it possible to estimate parameters that cannot be estimated at present ([Walpole et al., 2013](#)).

Due to their complexity, it is often impractical for one group to reproduce the numerical results generated from another group's multiscale model, unless they have access to their software. As a result, it can be difficult to establish, with confidence, whether particular features of a multiscale model

are responsible for observed behaviors. The introduction of standards for multiscale modeling, similar to those being developed by the systems biology community, could mitigate against such uncertainty. Equally, the creation of multiscale, benchmarking datasets would greatly facilitate model validation and comparison.

Summary

- Cellular systems are inherently multiscale and their multiscale nature needs to be considered in order fully to understand their complexity.
- Multiscale models provide a theoretical framework for studying complex biological systems and maximizing the information content of the diverse types of qualitative and quantitative data that can be collected.
- Multiscale models should be fully tested and validated against experimental data in order to establish confidence in the predictions that they generate.
- Comprehensive datasets are needed to benchmark and validate multiscale models.

Conclusions

As experimental techniques improve, and the quality, quantity, and diversity of biological data that can be collected increase, the demand for multiscale mathematical models that can systematically integrate these data and provide mechanistic insight into complex biological processes is set to increase. While still a relatively young discipline, the advantages and opportunities for vertical integration are becoming clear. There are still many areas of biological research where multiscale models are either few or nonexistent. This deficiency should be viewed as an opportunity to demonstrate how the boundaries of biological knowledge can be advanced by using multiscale modeling as a platform for high-throughput hypothesis generation and testing ([Walpole et al., 2013](#)).

Glossary

Agent-based modeling A specific discrete-based hybrid modeling approach that allows simulating single to multi-element groups and their interactions, thereby enabling the investigation of the role of diversity in populations as well as within each individual element.

Continuum modeling It describes biological tissue as a continuum medium, and thus is an appropriate choice for modeling larger-scale systems such as tissues or organs. This approach draws on principles from continuum mechanics to describe model variables and parameters as continuous fields mostly by means of differential equations.

Discrete modeling It explicitly represents individual model elements, such as cells or proteins, in space and time, and tracks and updates their internal states according to a

predefined set of biological rules. The computational demand increases rapidly with the number of elements and their interactions modeled, limiting these models in the spatial and temporal scales they can represent.

Hybrid modeling It integrates the strengths of both continuum and discrete descriptions. The complexity of any biological systems and the interactions among their constitutive elements calls for a combined continuum and discrete approach.

Multiscale modeling It describes and examines a biological system across two or more spatial and/or two or more temporal scales, and quantifies parameters on and relationships between biological processes that occur at those scales.

Introduction

A biological system is regulated at scales of many orders of magnitude in space and time, from genes and proteins, to cells, tissues, organs, and organisms (Hunter *et al.*, 2008). These different scales coupled with intra- and inter-scale interactions make any such system extremely ‘complex,’ in that the behavior of the emergent, larger-scale system cannot easily be understood by investigating its constituents only. For example, the dynamic interactions at the molecular scale are dominated by random and short timescale fluctuations, but are more deterministic with longer timescale variations at the organ or organism scale. The past two decades have seen significant advances in science and technology along with a rapid expansion of biological, biochemical, and biophysical data on any biological scale (Auffray *et al.*, 2009). However, researchers realize the difficulty of solely relying on experimental observations to understand, quantify, and predict the behavior of complex biological systems. As such, there has been lately substantially more development on the mathematical modeling and computer simulation side, together with traditional experimental and clinical investigations. Indeed, mathematical modeling has been used to provide quantitative insight into biological systems, guide the design of new experiments, introduces potential target candidates for further clinical investigation, and present novel integrated approaches to treat systemic disease.

In particular, systems biology, a new field of integrative research, takes advantage of both experiments and computational/mathematical modeling in an effort to reveal the complexity of biological systems and their behavior at multiple scales in normal and perturbed conditions (Kohl *et al.*, 2010). The key is to perform closely linked model-experiment

iterations for parameterizing and validating these quantitative models. By adopting an integrative approach (as opposed to the more traditional reductionist approach), systems biology aims to predict emergent behavior that will arise from the interactions over time, for example, between genes, proteins, cells, and tissue scales. More specifically, systems biology now seeks not only to understand events at the separate biological scales in a quantitative manner, but also to develop mathematical models which are coupled together to produce integrated approaches across scales, i.e., multiscale models. This integration across multiple scales introduces a powerful tool for capturing and analyzing biological data that is inaccessible through other modeling and experimental techniques. However, understanding, quantifying, and handling (1) the coupling mechanism across scales and (2) the resulting emergent structure and function is a very challenging task (Barabasi, 2005). Even though, multiscale modeling has made significant progress in modeling a variety of biological systems (De Graaf *et al.*, 2009; Engler *et al.*, 2009; Grima, 2008; Lowengrub *et al.*, 2010; Meier-Schellersheim *et al.*, 2009; Sanga *et al.*, 2007; Schnell *et al.*, 2007; Southern *et al.*, 2008; Tracqui, 2009; Qu *et al.*, 2011; Walpole *et al.*, 2013; Slood and Hoekstra, 2010; Hatzikirou *et al.*, 2012). The resulting integrated models, however, are often computationally expensive with exceedingly long runtimes, impossible to solve analytically and difficult to solve numerically even with the tremendous increases in computational power available today.

Despite the large body of literature on multiscale models, there seems to be a lack of discussion on specific methods and clearly specified development strategies for this approach. Since multiscale modeling needs to address the question of how to bridge the gaps between different modeling methods and between models at different scales, there is no

straightforward way to go from one scale to another, but there are useful methods that have been developed for this purpose. In this article, we first present a brief summary of the current multiscale modeling methods in the field of biomedical research. We then further discuss in more detail a number of computational methods and theories, including agent-based modeling (ABM), equation-free approach (EFA), and a dynamic hybrid modeling approach, which can be used to bridge these gaps.

Multiscale Modeling

There are a number of important facts we should state before introducing specific multiscale modeling methods. First, the remarkable increase in computational power has enabled modeling to advance from looking at simple phenomena in isolation to the analysis of complex coupled processes (Bradley *et al.*, 2011). Second, a multiscale model often originates through linking individual sub-models from two or more distinct scales to generate a composite system. The sub-models should be validated at each corresponding scale before validating the integrated model across the scales. Third, a good mathematical model (whether multiscale or scale-specific) should not just fit to a set of experimental or clinical data; rather it should help to explain the underlying mechanisms, and make testable predictions or generate experimentally testable hypotheses (Edgerton *et al.*, 2011; Pascal *et al.*, 2013a, b; Das *et al.*, 2013).

Overview of Current Modeling Methods

A multiscale model may require different mathematical descriptions at these various scales and it may necessitate different computational technologies. In general, smaller-scale processes are faster (i.e., small spatial scales and fast dynamics), so it is reasonable to assume that the smaller-scale processes are in quasi-equilibrium with the slower larger-scale (i.e., large spatial scales and slow dynamics) processes. Hence, smaller-scale processes are often included at the larger-scale via, for example, constitutive equations or force fields (Sloot and Hoekstra, 2010). Various methods have been developed for solving multiscale problems in many scientific areas (Schnell *et al.*, 2007; Southern *et al.*, 2008; Deisboeck *et al.*, 2011), including ‘continuum’ techniques where the relationship between system properties is expressed with continuous mathematical equations, ‘discrete’ techniques which are based on individual units to model the smaller-scale elements such as individual cells, and ‘hybrid’ techniques which combine aspects of both discrete and continuum modeling to provide a more complete description of a system. Perturbations of fine-grained parameters (e.g., cell division) can be used as inputs to generate observable and measurable changes to coarse-grained outputs (e.g., tissue patterning). Conversely, these coarse-grained parameters can also regulate the dynamics of certain fine-grained parameters.

Modeling approaches can also be broadly divided into two categories: ‘bottom-up’ and ‘top-down’; this classification method is more accepted by experimental and clinical

scientists in the field. The bottom-up (i.e., data-driven) approach studies individual elements and their interactions; however, it is computationally intensive which leads to limitations of the number of proteins, mechanisms, or cells that can be modeled at the same time. Another caveat is conceptually, as already mentioned earlier, in that the main characteristic of complex (biological) systems is that piecing its larger-scale functions together from simply monitoring (and modeling) its constituent elements will not succeed. Instead of looking at the details of each individual element, the top-down (i.e., theory- or expertise-driven) approach uses the macroscopic behaviors of the system as variables to model the system dynamics at a larger-scale, largely based on experimental observations. The advantage of the top-down approach is that it is relatively simple and more easily developed. The disadvantage is that the variables and parameters in these models are largely more phenomenological than those in the bottom-up models. Combinatorial concepts would train bottom-up models on macroscopic behaviors, or incorporate fine-grained components into top-down approaches.

Multiscale Modeling Methods

In the following, we introduce some specific multiscale modeling methods that are technically compelling and can be applied in a wide range of biomedical fields. Although for any method, we only describe its key development concepts, we encourage interested readers to refer to the original publications for further technical details. Interesting examples for each method will also be presented where appropriate.

Composite hybrid ABM

ABM is an approach for describing discrete stochastic biological processes as either compartmentalized or spatially defined models in one-, two-, and 3D domains (Byrne and Drasdo, 2009; Auffray *et al.*, 2009; Wang and Deisboeck, 2008). In an agent-based model, each biological cell is often represented as an agent; but this is not necessarily the case – an agent can be scaled as large (groups of organisms) or as small (molecular components) as is needed. The agents must follow some biological, data-supported rules in the course of a simulation, both for their independent behavior and for interactions with other agents and the environment. A serious problem in ABM is its high computational demand because of the large number of agents involved and the spatiotemporal fine-resolution they operate on. Efficient techniques for reduction of computational costs are therefore necessary to be able to use ABM to its maximum potential, en route to more clinically relevant applications. Several types of ABM techniques exist, including lattice-based, lattice-free, Cellular Potts, lattice-gas, and subcellular element modeling methods (Anderson *et al.*, 2007). A number of open-source ABM software packages are available also, facilitating the process of developing an agent-based model (see An *et al.* (2009) for an excellent review).

For instance, Xu *et al.* (2008) developed a 2D multiscale agent-based model using a parallel Cellular Potts model to study thrombus formation in a blood vessel. Many factors

were included in their model: an injury site in a vessel wall, platelets, coagulation factors, fibrin, blood cells, and blood plasma. Platelet movement was driven by plasma flow while platelets could bind to each other, and platelets at the wound could release factors that activate or recruit other platelets. Blood cells and quiescent platelets flow past the wound site, where the platelets can be recruited, activated, and stimulated to produce fibrin and attach to the growing thrombus. The model showed that there were different stages of thrombus formation that happened in sequence and at a fast timescale. They also observed that the thrombus size was influenced by the flow rate, i.e., it being too large or too small resulted in a diminished thrombus formation rate. Using a mouse model, these observations were confirmed experimentally by externalizing a vein and then adding fluorescent markers to the blood, injuring the vein with a laser, and studying it with confocal microscopy.

Wang *et al.* developed a 3D ABM spanning molecular signaling network and multicellular scales based on prior work (Wang *et al.*, 2007) to quantify and predict the relationship between extracellular stimuli, intracellular signaling dynamics, and multicellular lung cancer growth and expansion (Wang *et al.*, 2009). At the molecular scale, they implemented an epidermal growth factor receptor (EGFR) signaling pathway, triggered by multiple growth factors; at the multicellular scale, they constructed a lattice-based 3D heterogeneous biochemical microenvironment populated with growth factors, glucose, and oxygen. Each cell (agent) carries a self-maintained EGFR pathway, implying that cells will differ in signaling profiles and thus will exhibit varying phenotypic behaviors as the simulation progresses. To link molecular changes to cell phenotype determinations, the authors established a unique experimentally supported, molecularly driven cellular phenotypic decision algorithm based on experimental findings. Specifically, experimental studies have shown that the transient acceleration of accumulating phospholipase-C gamma-1 (PLC γ) levels leads to cell migration (Dittmar *et al.*, 2002), while that of extracellular signal regulated kinase (ERK) leads to cell replication (Santos *et al.*, 2007); both PLC γ and ERK are downstream signaling components of the EGFR pathway. Hence, the rate of change of PLC γ was used to determine the cellular migration decision and that of ERK to dictate the cellular proliferation fate. With this molecular-multicellular simulation platform, they were not only able to monitor multicellular dynamics in response to individual or combinatorial molecular changes, but could also track molecular signaling dynamics on a single cell level as the tumor system evolves. This model has also been used in identifying and validating potential therapeutic drug targets that are concurrently effective on both molecular and multicellular scales for cancer treatment (Wang *et al.*, 2008, 2011, 2012, 2014; Wang and Deisboeck, 2014). This was done by way of sensitivity analyses, i.e., by evaluating how changes occurring at the molecular level percolate across the scales of the model and affect tumor growth behaviors at the multicellular level.

In addition to these 'in-house' modeling studies, public available ABM software has also been widely employed in biomedical research. Using a Java-based Recursive Porous Agent Simulation Toolkit (RePAST) as a modeling framework, Tang *et al.* (2007) presented an agent-based model to describe

the dynamics of rolling, activation, and adhesion of individual leukocytes. Each leukocyte in their model is an object where intercellular processes were constant and membrane unit processes were executed autonomously. Leukocytes could make contact in a customizable 'contact zone,' which can be divided into arbitrary membrane units. The leukocytes can roll on the surface, bind to available ligands, and will be activated after binding; yet, these bonds can be broken as well. The authors performed separate simulations on leukocytes rolling with two ligands: P-selectin and VCAM-1, and found that the simulation results were comparable to experimental distance and velocity measurements made using a parallel-plate flow chamber. The authors concluded that their model will be useful for studying subcellular molecular events and changes that may be involved in phenotypic transitions that lead to disease-related adhesion.

EFA

The so-called EFA is a framework for computer-aided multiscale analysis, enabling one to perform macroscopic computational tasks (over long temporal and large spatial scales) by using only appropriately initialized microscopic simulations (on short time and small length scales). A key feature of this approach is that it eliminates the derivation of explicit macroscopic evolution equations (Kevrekidis and Samaey, 2009). This is very important because, for many biological systems, the evolutionary macroscopic behavior can be seen in practice but cannot be described in closed mathematical forms. The essential concept behind EFA is a coarse time-stepper, which performs those coarse-scale computations for systems that have been modeled at a finer scale (Kevrekidis and Samaey, 2009). The coarse time-stepper achieves a time step of an unavailable macroscopic model as a three-step process: coarse projective integration, gap-tooth scheme, and patch dynamic. Through these steps, the direct derivation of macroscopic equations is bypassed by using simulation results at a microscopic scale to estimate the behavior of the model at the macroscopic scale.

A group of animals can display different types of collective motion (e.g., schooling, flocking, and swarming) at different times. EFA has been used to analyze a 1D agent-based model of self-organizing group formation with stochasticity by bridging the agent-based model with coarse population-level analysis (Kolpas *et al.*, 2007). The stochasticity was introduced to the model by adding a small deviation to the heading of each agent obtained from a deterministic evolution algorithm. A framework was developed for coarse analysis of the stochasticity-induced switching between two metastable cohesive collective motion states: the stationary and mobile states. A lifting procedure was used to run simulations for brief bursts of time with the agent-based model at a given value of A , a 'coarse variable' that characterizes the long-term dynamics of the model. Through model analysis, the authors show that animal groups can frequently switch between the two different collective motion states due to stochastic effects, in addition to change of animal behaviors or environmental factors.

EFA has also been used to build efficient numerical algorithms to accelerate stochastic simulation of gene regulatory networks (Erban *et al.*, 2007). The authors combined EFA with a recently developed data mining technique, diffusion maps

(Coifman *et al.*, 2005), which can identify coarse-grained variables dependent on simulation data. Specifically, coarse-grained variables were first identified with the diffusion maps method. Short bursts of a full-scale run of a stochastic simulation algorithm (SSA; Gillespie, 1977) were then designed and processed. These bursts of SSA were then used to numerically solve the evolution equations for the coarse-grained variables. The authors analyzed a two-gene network (Gardner *et al.*, 2000) as an example where each represses the transcription of the other gene, and found through their analysis that the previously known variables were indeed significant coarse-grained coordinates. The authors claim that this combined ‘variable-free, equation-free’ analysis can be a promising approach for determining features of the long-time, coarse-grained behavior for certain classes of complex stochastic models, including gene regulatory networks, as an alternative to long, full-scale SSA simulations.

An adaptive combined cell-based and continuum approach

Othmer’s group has been investigating an adaptive hybrid modeling approach where both discrete and continuum representations of cells are chosen dynamically and adaptively (Kim *et al.*, 2007, 2011). Their approach has been primarily used to describe and understand solid tumors. Specifically, cells in the outermost proliferating region are treated individually as deformable ellipses. Such a treatment of the outermost zone permits the inclusion of critical cellular variables, such as cell cycle time, cell size, metabolic state, effect of stress on growth of cells, and biochemical and biomechanical interactions between cells and their surroundings. However, it would be both redundant and computationally too expensive to repeat the same treatment in other regions of the tumor. The quiescent zone and necrotic core are thus treated as homogeneous viscoelastic continua, but each with a different material property. Together, instead of treating the whole tumor mass as individual cells, the cell-based descriptions are restricted to a subset of cells (usually a relatively small number) only, without compromising the efficiency and accuracy of the model. The reaction-diffusion equations for oxygen and glucose are normally solved for the entire domain. By including alterations in cell-scale parameters and material properties of continuum regions, the effect on tumor behavior and growth can be investigated.

This adaptive hybrid approach has been applied to ductal carcinoma *in situ* for studying the interactions of epithelial cells within breast ducts with the tumor microenvironment, and to understand how these interactions affect tumor growth and development (Kim and Othmer, 2013). The epithelial cells and transformed epithelial cells were all treated with the cell-based approach rather than discretizing them into zones of proliferation, quiescence, or necrosis. Their temporal evolution was determined similarly to that of proliferating cells in a spheroid. The microenvironment surrounding the duct is modeled as a continuum with the fibroblasts and myofibroblasts assumed as point sources or sinks of growth factors. Mechanical force balance and reaction-diffusion equations governed the evolution of growth factors, like EGF and transforming growth factor- β (TGF- β). This model also provided insight into potential therapeutic interventions that are beyond the conventional therapeutic targets of killing tumor cells. Model results demonstrate

that blocking signaling pathways involving TGF- β could delay transformed epithelial cell activation and thus restricted their population. The model highlighted the potential of tumor stroma as a target for manipulating host–tumor interactions to prevent tumor invasion. This model can also serve as a platform for understanding biomechanics of tumor cell invasion through the basement membrane and the role of proteinases secreted by fibroblasts and tumor cells.

Brief introduction of mean field theory, heterogeneous multiscale method, and dynamic density functional theory

Mean field theory is a method derived from statistical physics for reducing a high-dimensional problem into a low-dimensional one with macroscopic variables and has been widely used in modeling a variety of biological systems (Baker and Simpson, 2010; Cui *et al.*, 2009; Loew *et al.*, 2009; Naundorf *et al.*, 2006; Rovetti *et al.*, 2010). This method assumes that all the elements involved in a system can be controlled by a single mean field. It has been proven that this method can produce accurate results when the elements are globally coupled or when the system is well mixed, but when the temporal and spatial fluctuations of those elements are large, the mean field representation becomes inaccurate. Nevertheless, mean field theory is a good approximation under many conditions and can provide mechanistic insights. One may be able to employ this method to develop a useful low-dimensional representation of a high-dimensional system, which would be very valuable for multiscale modeling. Other innovative multiscale modeling methods, including the heterogeneous multiscale method (HMM; E *et al.*, 2003, 2007) and the dynamic density functional theory (DDFT; Chauviere *et al.*, 2012), have also been used to functionally link biological processes that occur at different scales. In particular, the capability of the DDFT approach in capturing multiple sources of nonlinearity from the spatiotemporal heterogeneity of soft tissue can be very helpful for modeling heterogeneous tissues (such as a tumor).

Discussion

The complexity of a biological system has made the use of mathematical and computational models, along with the analysis of their behavior and functions, an active area of research in recent years. However, any such system’s emergent behavior is highly unpredictable by a traditional modeling approach where hypothesis testing assumes that the modeler has a ‘clear’ idea of how the system functions (Holcombe *et al.*, 2012). Due to the multiscale nature of biological systems, one must link its physiological processes that occur at different scales in a consistent manner, so that the information from a smaller scale can be carried over into the simplified model of a larger scale (Kohl and Noble, 2009). Reality, however, is that there are many open avenues of research where multiscale efforts are either sparsely represented or completely nonexistent. This then presents an opportunity to push the boundaries of knowledge in these biomedical investigations, using multiscale modeling as a platform for hypothesis generation and testing. Overall, multiscale modeling offers computational biologists the unique advantage of being able to introduce perturbations across any tier of resolution (Vicini, 2010).

We have introduced a number of advanced multiscale modeling techniques. However, one has to keep in mind that under any circumstances, as with any advanced method, multiscale models introduce certain simplifications to render them computationally feasible. Hence, validation of these models is required to test the reliability of data transfer and the adopted cross-linking methods between its scales. As with other modeling efforts, a comprehensive validation is critical to achieve acceptance in the community by experimental scientists and clinicians (Koay *et al.*, 2014). Given that in many situations, experimental cross-scale data are still difficult to find or simply unavailable, one may perform cross-validation to prove the predictive power and reliability of the model, i.e., using different modeling methods to examine the same biological system (Andasari *et al.*, 2012).

The roles of standards in multiscale modeling cannot be underestimated. Standards such as SBML (Hucka *et al.*, 2003), CellML (Lloyd *et al.*, 2004), and FieldML (Christie *et al.*, 2009) have begun to play important roles in multiscale modeling (Popel and Hunter, 2009). Having the models, data, and metadata available in standardized formats with clearly stated dependencies will improve the utility of models and facilitate the creation of powerful workflows for comparing model predictions with experimental data (Sloot and Hoekstra, 2010). Furthermore, the simulation of large-scale multiscale models (e.g., the IUPS Physiome project (Hunter, 2004)) will likely have to span several (academic, governmental, and commercial) organizations, thus requiring efficient integration and management of models (and associated data), from creation and initial storage, to revision, up to the time when a model becomes obsolete and is deleted. Web services offer a flexible means of integrating often incompatible applications and tools for data acquisition, registration, storage, provenance, organization, analysis, and presentation (Wang *et al.*, 2013).

In summary, successful analysis of any biological system requires a better understanding of the functional interactions between the key components of molecules, cells, and organs, as well as how these interactions change in disease states. By drawing on the strengths of the powerful multiscale methods introduced herein and integrating them into the next generation of simulation workflows, we will be able to produce computationally more efficient models to more accurately describe and to better simulate biological processes of interest, and to plan for and predict treatment impact more successfully.

State-of-the-Art in Cardiac Cell Modeling

In 1960, Denis Noble developed the first mathematical model of the electrophysiological activity of a cardiac cell (Noble, 1960). Since then, the field of computational cardiovascular science has developed into a broad and productive area of research with growing demonstration of translational potential into industrial, regulatory, and clinical applications (Sager *et al.*, 2014). Computational heart models are multiscale both spatially and temporally, and integrate information across subcellular, cellular, tissue, and whole organ levels, and temporal scales (ranging from picoseconds to years, from ion channels opening and closing to remodeling in disease). Through continuous use and refinement, computational cardiac cell models have built a strong basis for their usefulness and credibility in a variety of settings, including investigations of genetic mutations, disease, and pharmacology (Clancy *et al.*, 2007; Sarkar and Sobie, 2011; O'Hara and Rudy, 2012; Wilhelmms *et al.*, 2012a,b; Britton *et al.*, 2013; Zemzemi *et al.*, 2013; Polak *et al.*, 2014).

Cardiac cells (cardiomyocytes) are electrically excitable cells due to the presence of proteins in their membrane which act as mechanisms of ionic transport, such as ion channels, pumps, and exchangers. The transmembrane transport of ions such as potassium, sodium, and calcium results in electrical and concentration gradients between the intracellular and the extracellular media. Under physiological conditions with no external electrical stimulation, cardiomyocytes maintain a negative voltage relative to their environment. However, when stimulated, sodium channels in the cell membrane are activated, altering the balance of currents into the cell and acting to rapidly change the electrical potential across the membrane. This triggers the release of calcium ions from a cellular compartment known as the sarcoplasmic reticulum, which raises the bulk cytoplasmic concentration of calcium and signals the myocyte to contract. The ion channels initially responsible for firing the action potential inactivate, while others (potassium) act to repolarize the myocyte back to its resting potential. This allows the cardiomyocyte to fire another action potential during the next heartbeat. In this manner, the cardiac action potential, first observed by Coraboeuf and Weidmann (1949), allows the heart to control its own pattern of muscular contraction without external stimuli. The action potential generated by each cardiomyocyte can excite nearby myocytes, and thus the electrical signals propagate through the heart.

In the last of a landmark series of papers, Hodgkin and Huxley (1952) showed that their mathematical model of the ionic currents of the isolated squid giant axon could recreate many of the axon's key electrical properties. This was the first mathematical model of a neuronal action potential. Their formulation of ion channel kinetics was promptly adapted to create the first action potential model of a cardiac cell (Noble, 1960). The Hodgkin–Huxley model formulates each ionic current as the product of the permeability of the cell

membrane to the ion type of that current (more commonly called the conductance of that current), multiplied by the difference between the membrane potential and the equilibrium potential for that current (the membrane potential at which the net current flow across the membrane for that ion is zero). The conductances are functions that may depend on membrane potential and time, as well as channel-specific constants. They represent the opening, closing, and inactivation of the ion channels that carry current across the cell membrane.

Cardiac cell electrophysiology models, from the very beginning of the field up to the present day, have used the Hodgkin–Huxley formulation to describe the ionic currents in the model. An alternative approach to describe ion channel gating is the use of Markov chain models (Greenstein *et al.*, 2000; Mazhari *et al.*, 2001; Clancy and Rudy, 2002), which model the transition between the open, closed, and inactive states of the channel, based on the probabilistic transition rates between channel states at different transmembrane potentials.

From the earliest models that were very closely based on the original three current Hodgkin–Huxley model, new models have increased in complexity, based on our growing understanding of cardiac cellular electrophysiology, for example, the discovery of calcium channels. In general, the additions made in each new model have been in one or more of the following forms: (1) additions of new currents carrying ions such as calcium, (2) addition of new gating mechanisms for existing currents, (3) subdividing a single current into multiple currents either because of different time scales for the parts of the current (e.g., the fast and late sodium currents) and/or because different ion channel proteins carry the different components (e.g., slow and rapid delayed rectifier potassium currents), (4) addition of mechanisms relating to intracellular ionic concentrations (e.g., adding ion transporters such as the sodium–potassium pump or new cellular compartments such as the sarcoplasmic reticulum for calcium handling), and finally (5) adding biochemical mechanisms for ion channel modification, contraction, or signaling, such as, for example, models of beta-adrenergic stimulation (Kuzumoto *et al.*, 2008; Heijman *et al.*, 2011) or ion channel regulation by calcium/calmodulin-dependent protein kinase II (Christensen *et al.*, 2009; O'Hara *et al.*, 2011; Koval *et al.*, 2012). The formulation of the different ion channels and transporters is usually inherited between models, although particularized for the specific cell type and species under study (Niederer *et al.*, 2009; Bueno-Orovio *et al.*, 2014b). This is illustrated in Figure 1 for the particular case of the sodium–potassium pump.

Computational cardiac models have played a pivotal historical role in the discovery of new ionic mechanisms through successes and failures in reproducing and challenging experimental evidence (Noble, 2011). As *in silico* models and simulation techniques developed both conceptually and

Figure 1 Inheritance in the formulation of the sodium-potassium pump current in a selection of models of cellular cardiac electrophysiology. Models are referred by first author's name and year of publication. The complete list of references can be found in (Noble *et al.*, 2012). Reproduced with permission from Bueno-Orovio, A., Sánchez, C., Pueyo, E., Rodríguez, B., 2014b. technically, the questions of verification, validation, and uncertainty quantification have become crucial for their uptake beyond scientific research into industrial, clinical, and regulatory arenas (Carusi *et al.*, 2012; Sager *et al.*, 2014; Wallman *et al.*, 2014; Pathmanathan *et al.*, 2015).

The process of validation of *in silico* models and simulations is complex and still under investigation, but it is essential to increase the credibility of *in silico* methods as powerful techniques to augment the information extracted from experimental and clinical investigations. The paper by Carusi *et al.* (2012) specifically explores the issue of validation of computational physiological models in the context of their construction and applications. It highlights the iterative nature of the process of validation and the fact that it needs to consider the ensemble of equations, parameters, simulation techniques, software, and experiments used for a particular study or purpose, namely the Model-Simulation-Experiment system. The aim is to augment the information on the physiological system or process under investigation, such as, for example, the mode of action of a new medicine on specific organs. The dynamics of the iterative process are driven by advances in both experimental and computational techniques, as well as investigations on their combined use.

The legacy of such intense work is over 40 available mathematical models of cardiac cellular electrophysiology, for

different species and cell types (see Noble *et al.* (2012) for a comprehensive historical overview). The iterative process between models, simulations, and experiments leads to the dynamic replacement, refinement, and expansion of these models. In this context, initiatives such as the CellML repository provide the platform that allows the exchange and widespread use of cardiac cell models within the scientific community (Beard *et al.*, 2009).

Human Models of Cardiac Cell Electrophysiology

Computer modeling of the human heart has been a key priority for the scientific community as it provides a vital tool for a better understanding of human health and disease in clinical and industrial applications. Over the last decades a number of models of human adult electrophysiology have been proposed for both ventricular and atrial cells. Biophysically detailed models represent biophysical processes such as ion transport across the membrane and intracellular calcium handling, which are described by equations that represent individual ionic currents and fluxes. A different approach is based on phenomenological models, which reproduce the electrophysiological behavior of cardiac cells without detailed modeling of the underlying biophysical processes. These models

Figure 2 Schematic diagram representations of models of human cellular cardiac electrophysiology. (a) O'Hara-Rudy model of the human ventricular cardiomyocyte. (b) Comparison of different models of human atrial cellular electrophysiology. Reproduced with permission from O'Hara, T., Virág, L., Varró, A., Rudy, Y., 2011. Simulation of the undiseased human cardiac ventricular action potential: Model formulation and experimental validation. *PLoS Computational Biology* 7, e1002061; Wilhelms, M., Hettmann, H., Maleckar, M.M., *et al.*, 2012a. Benchmarking electrophysiological models of human atrial myocytes. *Frontiers in Physiology* 3, 487.

require fewer equations and parameters, and are ideal for applications that do not necessarily require the representation of ionic processes, such as the impact of cellular level properties on the cardiac electrical propagation at the tissue level.

Several human ventricular and atrial cell models have been proposed and compared over the last two decades. Their structure is illustrated in Figure 2, through a schematic representation of the O'Hara-Rudy human ventricular model (O'Hara *et al.*, 2011), and a graphical comparison of the ionic currents included in different human atrial models (Wilhelms *et al.*, 2012a,b). Human ventricular cell models include the biophysically detailed Priebe and Beuckelmann (Priebe and Beuckelmann, 1998), Iyer (Iyer *et al.*, 2004), ten Tusscher and Panfilov (ten Tusscher *et al.*, 2004; ten Tusscher and Panfilov, 2006), Grandi (Grandi *et al.*, 2010), Carro (Carro *et al.*, 2011), O'Hara-Rudy (O'Hara *et al.*, 2011), and Asakura (Asakura *et al.*, 2014) models, as well as phenomenological models for human ventricular myocardium (Bueno-Orovio *et al.*, 2008; Bueno-Orovio *et al.*, 2012). Equivalently, several models of human atrial electrophysiology have been published such as the Nygren (Nygren *et al.*, 1998), Courtemanche (Courtemanche *et al.*, 1998), Maleckar (Maleckar *et al.*, 2009), Grandi (Grandi *et al.*, 2011), and Koivumäki (Koivumäki *et al.*, 2011) models. The phenomenological Bueno-Orovio model has also been adapted to reproduce characteristic action potentials of human atrial tissue (Weber *et al.*, 2008). Comprehensive comparisons between these ventricular and atrial human models can be found, for example, in Bueno-Orovio *et al.* (2008), Wilhelms *et al.* (2012a,b), and Elsharif and Cherry (2014).

Modern human cardiac cell models consist of a system of ordinary differential equations, generally based on the Hodgkin and Huxley or Markov chain formulations for ionic gating variables. As shown in Figure 2, a number of biophysical components are represented, including ionic currents and cellular compartments. Ionic currents that are usually included in human ventricular cell models are the sodium current (I_{Na}), sometimes divided on its fast (I_{NaF}) and late (I_{NaL}) components; the L-type calcium current (I_{CaL}); the transient outward potassium current (I_{to}); the rapid (I_{Kr}) and slow (I_{Ks})

delayed rectifier potassium currents; the inward rectifier potassium current (I_{K1}); the sodium-calcium exchanger current (I_{NCX}); and the sodium-potassium pump current (I_{NaK}). Human atrial cell models incorporate additional ionic currents specific to atrial electrophysiology, such as the ultra-rapid delayed rectifier (I_{Kur}) or the acetylcholine activated (I_{ACh}) potassium currents, as well as differences in calcium handling between ventricular and atrial cells (Figure 2). Usually these models contain at least three compartments, the bulk cytoplasm, encompassing the bulk of the cell and the majority of the cell membrane, where most ionic currents enter or exit the cell and where intracellular sodium, calcium, and potassium ionic concentrations are modeled; a cytoplasmic subspace representing the space near the T-tubules, through which the L-type calcium current flows; and one or more compartments comprising the sarcoplasmic reticulum, with modeled uptake of calcium ions from the bulk cytoplasm by sarco/endoplasmic reticulum Ca^{2+} -ATPase (SERCA) and release into the subspace compartment by calcium-induced calcium-release through ryanodine receptors. Other currents, biochemical and signaling processes, and cellular subdivisions exist, but these differ from model to model.

Modeling Variability in Cardiac Cell Electrophysiology

Variability is essential to biology. No two measurements are the same, no two individuals are the same, and even the same individual will change over time due to aging, disease, or the environment. This variability is exhibited at all biological levels, from cells to organs, with broad implications in our individual response to disease or drug action. However, intersubject variability is usually combined with measurement errors in experiments, and expressed as part of the error in mean values of measured quantities. This permeates into computational models of cardiac cellular electrophysiology, which are commonly fitted to the mean data, therefore representing an 'average' individual.

As discussed in the previous section, cellular cardiac models consist of a system of ordinary differential equations, with

a set of parameters controlling the magnitude and kinetics of the ionic currents included in the model. A common assumption is that variability enters the model at the level of parameters and not at the level of equations. That is, for a specific cell type under investigation, the biophysical processes are the same between individuals, but the quantitative properties of their ionic currents may differ. Two main approaches probing variability in this manner have been described in the literature: these are sensitivity analysis and population of models-based methods.

Sensitivity analysis methods are those where one or more parameters are varied around an existing parameter set (most often the original published parameter set of the model), to quantify the effect this has on model outputs. This approach has been used in cardiac electrophysiological studies. Romero *et al.* (2009) performed a single parameter sensitivity analysis and compared the results to experimental measurements, in order to determine the impact of variability in human ventricular ionic properties on important preclinical biomarkers of arrhythmic risk. In contrast, Sobie (2009) varied multiple parameters simultaneously in a variety of ventricular cell models by sampling their values from a statistical log-normal distribution, centered at the original parameter values (Sarkar and Sobie, 2011; Sarkar *et al.*, 2012). Following this, they used a multivariate regression analysis to relate changes in parameters to model outputs. Using similar methods, Walmsley *et al.* (2013) investigated the role of mRNA expression levels (genetic messengers of ion channel expression in the cell membrane) on electrophysiological remodeling in failing human hearts. More recently, these techniques were used by Cummins *et al.* (2014), who compared 13 ventricular cell models in the context of drug action at different stimulation frequencies.

The second methodology used for modeling intersubject variability is to create and analyze experimentally calibrated populations of models (Britton *et al.*, 2013). To generate a population of models, a subset of the model parameters are varied within the population, based on the parameters known or hypothesized to vary most between individuals, and sampled using random methods such as Monte Carlo or Latin hypercube sampling (McKay *et al.*, 1979). These parameter sets are subsequently inserted into the model equations and simulated. Experimental calibration is then conducted by imposing the requirement that all the considered action potential properties must lay within the experimentally observed bounds, for all the simulated protocols. Therefore, models that are not fully consistent with the experimental data are discarded from the population. This is referred to as the calibration step, and is the major difference between the population of models and sensitivity analysis-based methods. The ensemble of models in full agreement with the experimental data is termed the experimentally calibrated population of models, and used for further investigations. Figure 3 illustrates simulated action potential traces using an experimentally calibrated population of human atrial models (Sánchez *et al.*, 2014).

The population of models approach was originally developed in the field of neuroscience (Prinz *et al.*, 2003; Taylor *et al.*, 2009; Marder and Taylor, 2011). Its use in cardiac electrophysiology was pioneered by the work of Britton *et al.*

(2013), who also demonstrated its quantitative predictive power under pharmacological action. The approach has later been applied to investigating sources of variability in cellular repolarization in rabbit ventricular electrophysiology (Gem-mell *et al.*, 2014), mechanisms of human intersubject variability in sinus rhythm versus chronic atrial fibrillation as illustrated in Figure 3 (Sánchez *et al.*, 2014), and the investigation of pro-arrhythmic mechanisms in human hypertrophic cardiomyopathy (Passini *et al.*, 2014), among others. A study by Davies *et al.* (2012) also used a population of models approach to create representative parameter sets for each of the individuals in their dataset. These studies illustrate some of the different ways in which populations of models can be used to address diverse research questions, depending on the question being asked and the experimental data that is available.

Another source of variability in cardiac electrophysiology is the temporal or beat-to-beat variability of the action potential, which is modulated by disease and pharmacological drug action (Hondeghe *et al.*, 2001; Thomsen *et al.*, 2004; Myles *et al.*, 2008; Hinterseer *et al.*, 2010; Johnson *et al.*, 2010). Recent simulation studies using stochastic cardiac models provide supporting evidence to the contribution of the intrinsically stochastic dynamics of cardiac ion channels to beat-to-beat variability and repolarisation abnormalities under pharmacological action (Lemay *et al.*, 2011; Pueyo *et al.*, 2011; Heijman *et al.*, 2013). Interestingly, these instabilities are modulated and suppressed by intercellular tissue coupling, highlighting the multiscale nature of sources and modulators of cardiac variability (Pueyo *et al.*, 2011). These results also highlight the importance of multiscale simulations in elucidating the complex interplay of mechanisms determining the spatio-temporally dynamic and variable response of the human heart.

Whole Organ Cardiac Modeling

Cardiac cell models are often embedded in tissue and whole organ preparations in order to investigate the impact of ionic alterations on the propagation of electrical excitation in health and disease. Tissue and whole organ models have been extensively used in computational cardiovascular science during the last 15 years, as recently reviewed, for example, in Trayanova (2011) and Smaill *et al.* (2013).

Simulations of cardiac electrophysiology at the tissue and whole organ levels require mathematical modeling of the processes underlying intercellular electrical coupling and propagation of electrical excitation from cell to cell through cardiac tissue. The cardiac bidomain model is currently the gold standard, and arises by representing the cardiac tissue as a continuum with the intracellular and the extracellular spaces electrically connected through the membrane of cardiomyocytes (Tung, 1978). The bidomain model consists of two partial differential equations representing the tissue electrical properties in the intracellular and extracellular domains, coupled through the system of ordinary differential equations representing the membrane kinetics (as described in the previous sections). The partial differential equations assume that cardiac tissue is a continuum and are derived using two fundamental laws: Ohm's law (relating electrical potential to the

Inter-subject variability in human atrial action potential in sinus rhythm versus chronic atrial fibrillation. PLoS ONE 9, e105897.

net flow of transmembrane, intracellular, and extracellular currents) and Kirchhoff's law (for conservation of charge).

Generating solutions of the bidomain equations is computationally expensive, requiring application of sophisticated numerical techniques, such as the finite element method. Simplified formulations of the bidomain equations have been derived to decrease the high computational expense of numerical simulations, and alternative formulations include the monodomain and the Eikonal equations, as well as graph-based methods (Potse *et al.*, 2006; Wallman *et al.*, 2012). Novel modeling approaches considering fractional diffusion models have been recently applied to cardiac modeling (Bueno-Orovio *et al.*, 2014a). Pushing the boundaries beyond the perfect continuum assumption behind the bidomain equations, fractional diffusion cardiac models aim to capture

the effects of the heterogeneous microstructure of cardiac tissue, and therefore allow to investigate implications of heterogeneity in cardiac electrophysiological behavior.

Multiscale whole organ simulations of cardiac electrophysiological behavior also require the definition of spatial tissue characteristics such as its geometry, which are defined by a mesh. Anatomical meshes of the ventricles and the atria are obtained from cardiac magnetic resonance, computer tomography, or histology datasets, using image processing and mesh generation techniques (Bishop *et al.*, 2010; Vadakkumpadan *et al.*, 2010; Bordas *et al.*, 2011; Zhao *et al.*, 2012). The processed images are then used to generate a volumetric mesh by applying a discretization process in space, determined by the numerical method used to solve the propagation model equations (e.g., the finite element method for the bidomain equations).

Figure 4 Multiscale simulations of drug-induced effects on the human heart: from drug-ionic current interactions to body surface potentials. (a) Cross-section of the human ventricular model showing the distribution of simulated activation times across the ventricular wall and on the endocardium. (b) Distribution of the body surface potential in the human torso model. (c)–(h) Human ventricular action potentials (c) and electrocardiograms ((d)–(h)), simulated for different degrees of block of L-type calcium and hERG potassium currents (drug dose indicated as a function of the half maximal inhibitory concentration, IC_{50}). Reproduced with permission from Zemzemi, N., Rodriguez, B., 2015. Effects of L-type calcium channel and human ether-a-go-go related gene blockers on the electrical activity of the human heart: A simulation study. *Europace* 17, 326–333.

As a representative example, [Figure 4](#) illustrates simulations of the effects on the body surface electrocardiogram of drug action in calcium and potassium channels, using a multiscale human whole ventricular model with biophysically detailed representation of membrane kinetics, and embedded within a human torso ([Zemzemi and Rodriguez, 2015](#)). This figure exemplifies the potential that these novel technologies have in shaping the future of cardiovascular science. *In silico* modeling in biomedical applications is a research priority that can contribute to improvements in achieving a faster and cheaper drug development process, the reduction of medication errors and adverse side events, and the design of a more personalized healthcare.

Conclusions and Outlook

In this article we have described how cardiac modeling has developed from single cell models of a few cell types into a field with a wide variety of biophysically detailed single cell, tissue, and whole organ models, with a particular focus on models of human physiology. We have also described the importance of phenomena such as intersubject variability in cellular cardiac electrophysiology and heterogeneity in the structure of cardiac tissue, which contribute to variability in the responses of different hearts and patients to drugs and disease, and we have provided an overview of recently developed methods designed to probe both the sources and the consequences of such intersubject differences.

These recent advances in both models and modeling frameworks allow us to investigate how different phenomena interact and affect cardiac behavior at multiple spatio-temporal scales, ranging from single cells, through tissue, to the whole heart, as well as from picoseconds to years, thus opening new avenues to identify key determinants of the electrophysiological activity of the heart in health and disease. A major focus in cardiac modeling is its integration with experimental and clinical research in order to better explain and predict the effects of complex drugs, diseases, and genetic mutations on the human heart. In line with this, computational cardiovascular science is evolving beyond the traditional single physiological human paradigm to construct patient-specific or subpopulation-specific models of whole organ and single cells, respectively. In doing so, we hope to better understand the currently unpredictable risks of lethal pathologies in patients, and enhance prevention and treatment strategies.

Introduction

It is now clear that inflammation, the process by which a tissue responds to injury or infection, is central to the pathogenesis of a broad spectrum of diseases, including rheumatoid arthritis (RA), inflammatory bowel disease, asthma, atherosclerosis, neurodegenerative diseases, and also the development and metastasis of tumors (Medzhitov, 2010). This appreciation of inflammation's relevance has resulted in an increase in interest in studying the underlying cellular and molecular mechanisms of inflammation and, in concert with this, there has been a corresponding growth in interest in mathematically modeling the processes involved. Different approaches to modeling the inflammatory process range from inflammation being the sole target of mathematical and computational models to the key cell types and mediators involved in inflammation being captured in models of different disease scenarios (see Figure 1). Inflammation is a complex, highly regulated process that has components which interact on multiple time and space scales. The different temporal and spatial scales that are inherent in considering inflammation at a molecular, cellular, organ, or whole organism level, as well as the close interaction between inflammation and many other disease processes, make it challenging to study biologically and mathematically. Furthermore, despite recent progress in defining the contribution of different processes, such as leukocyte recruitment, cellular activation, and cell death, the precise interactions of these various elements of inflammation remain to be defined, potentially representing a constraint on the development of new effective therapeutic strategies. Combined mathematical and biological approaches can provide a new way to understand multi-scale systems such as inflammation, linking events over disparate time and space scales that are difficult to model with conventional microbiological or immunological experimental approaches alone (Figure 1).

Inflammation is characterized by key cellular and molecular events that occur in a distinct temporal framework. In response to an injury and/or infection, inflammatory mediators (lipids, peptides, and proteins) are produced that result in alteration of cellular responses (cellular activation) which can promote further inflammatory mediator production (Nathan, 2002). The earliest changes associated with the inflammatory process are vascular alterations, increased blood flow (vasodilatation), and vascular leak (edema) that represent one of the cardinal signs of inflammation (Kvietys and Granger, 2012). In addition, the activation of endothelial cells that line the blood vessel wall promotes the adhesion and subsequent recruitment of inflammatory leukocytes, particularly neutrophil and eosinophil granulocytes (Ley *et al.*, 2007). These cells have an important function in providing 'innate' host defense until a specific 'adaptive' response (which involves development of specific antibodies and cytotoxic lymphocytes) against the invading microorganisms (Kolaczowska and Kubek, 2013). Following removal of the inflammatory stimulus, recruited leukocytes either exit the tissue via the draining lymphatics or undergo a process of programmed cell death (apoptosis) which serves to package the potentially destructive intracellular contents for 'disposal' by other phagocytic cells that are present at the inflammatory site (macrophages) (Fox *et al.*, 2010). Removal of apoptotic cells and the subsequent reprogramming of macrophage function is thought to represent a critical factor for the termination of inflammatory responses (Savill *et al.*, 2002). In addition, macrophages have a pivotal role in tissue regeneration and repair that is required for restoration of normal organ function.

A systems-biology approach aims to utilize mathematical and computational techniques to understand biological processes in a dynamic manner (Kohl *et al.*, 2010). In this article, we will demonstrate the utility of the systems-biology approach in studying inflammation by formulating a simple mathematical model capturing a small subset of the complex

Figure 1 The inflammatory system responds to many different stimuli, and varies in its response according to tissue type. It plays a role in perpetuating, as well as being stimulated by, many different diseases. Its response is dependent on interactions that occur over many time and space scales from subcellular and cellular to tissue and organ specific responses. These complications result in inflammatory responses being often modeled generically (capturing key interactions common across tissue type and disease scenario) as well as being incorporated in models that are tailored to specific tissue types or disease scenarios.

interactions responsible for the successful resolution of inflammation. We then review some current mathematical and computational models that attempt to capture the inflammatory process, both in its generic form and as a key feature of, or as a stimulus to many of the disease scenarios in which inflammation plays a role. In doing this, we will demonstrate how mathematical modeling and computational techniques provide useful insights into this complex process that is central to so many diseases.

A Simple Mathematical Model Capturing the Resolution of Inflammation

Inflammation is a homeostatic process that is initiated in response to tissue injury, damage, or microbial attack. The cellular

and molecular events that ensue act cooperatively to eradicate pathogenic microorganisms, repair tissue damage, and restore normal tissue architecture. In health, inflammation resolves quickly, restoring normal tissue and organ functions. However, it has long been known that inflammation can be dysregulated, leading to a self-perpetuating chronic condition that plays a significant role in a broad spectrum of disease conditions, including those that were originally thought not to have an inflammatory component (Libby, 2002; Rogers *et al.*, 2007; Trinchieri, 2012). Although the historical view was that inflammation gradually 'subsided,' it is now evident that successful resolution of the inflammatory response is an active program of events that drive a switch from pro-inflammatory signals toward those of an anti-inflammatory nature (Serhan and Savill, 2005). The importance of an active inflammatory resolution process is reflected by the drive to identify new therapeutic agents that

Figure 2 A simple mathematical model capturing the basic interactions central to the resolution of inflammation. (a) A graphical representation of the mathematical model. Neutrophils (N) and macrophages (M) arrive at a site of injury in response to an inflammatory stimulus ($f(t)$). Neutrophils contain toxic chemicals that they release to kill pathogens; these can cause damage to healthy tissue, perpetuating the inflammatory response while macrophages phagocytose neutrophils. (b) The ordinary differential equations that capture the interactions just described. (c) Model simulations demonstrating the time-dependent cell concentrations in response to different amounts of tissue damage. If the injury is of a short duration (top row) all cells leave the tissue (a healthy response); otherwise inflammation can progress to a self-perpetuating chronic condition (middle row). Under a number of clinical conditions, the inflammatory response is impaired. Simulations (bottom row) demonstrate how reducing the rate of macrophage phagocytosis (one order of magnitude) can lead to the inflammatory system failing to recover from an injury of a short duration.

target resolution mechanisms that could be used in the treatment of chronic conditions. One pivotal factor in this switch is thought to be dependent on the interaction between the two major cell types involved in inflammation: neutrophils and macrophages (Silva, 2009).

As an illustration of how mathematical approaches can be utilized to effectively model inflammation and, in particular, can capture active pro-resolution pathways that may determine whether the inflammatory response ultimately returns to a healthy state or progresses to a chronic self-perpetuating injurious condition, we present a toy model based on earlier work (Dunster *et al.*, 2014) in the form of ordinary differential equations. This dynamic model captures some of the key interactions between neutrophils and macrophages (see Figure 2) that occur in response to a stimulus such as tissue damage. In brief, in response to an injury/infection stimulus, there is recruitment of both neutrophils and macrophages, resulting in increased numbers of cells present. Neutrophils destroy invading microorganisms by release of toxic chemicals. However, these can also cause damage to healthy tissue which would act to perpetuate the inflammatory response. Countering these pro-inflammatory events is the ‘silent’ removal of neutrophils by macrophages, a process involving neutrophil cell death and subsequent phagocytosis by a mechanism that contributes to the resolution of inflammation. Successful resolution of inflammation results in the clearance of all macrophages and neutrophils from the tissue (a healthy response). In contrast, development of a self-perpetuating

chronic condition is characterized by the persistence of recruited inflammatory neutrophils and macrophages (Figure 2).

The model presented represents an example of a bistable system with two distinct outcomes in response to an injury stimulus: resolution of inflammation (all cells return back to a healthy level) or chronic self-perpetuating inflammation (cells attain a metastable higher positive value). In this model, a low level of damage results in the former but, if a threshold of damage is passed, then the ultimate outcome is the latter. In Figure 2(c) (top row), we present simulations of the model showing a typical response to one cycle of damage. The damage stimulus causes the infiltration of both neutrophils and macrophages. Macrophages have the capacity to remove neutrophils and cell numbers ultimately return to a healthy level. In contrast, with the same parameter values, repeated cycles of damage (Figure 2(c), middle row) results in failure of macrophages to remove all neutrophils as inflammation progresses and as a consequence, both cell types settle to a positive steady state that we interpret as chronic inflammation. By varying the model parameters we can simulate a scenario in which the inflammatory system is impaired, such as would occur under disease conditions. In Figure 2(c) (bottom row), we present simulations in which the rate at which macrophages are able to remove neutrophils is reduced (all other parameters stay the same as previous simulations). In contrast to simulations in which inflammation resolves (top row), a single cycle of damage now results in accumulation of

both macrophages and neutrophils that we equate to failure to resolve inflammation and establishment of chronic inflammation. Computational models such as this could be utilized to not only simulate outcomes of manipulation of key parameters that could be altered in disease conditions but also in response to therapeutic agents. Such an approach would provide important insights into the potential impact of changes in rates of cell recruitment and clearance on the development and termination of an inflammatory response and importantly, the magnitude of change that would be required to afford therapeutic gain.

Current Mathematical and Computational Models of Inflammation

Existing mathematical and computational models of inflammation reflect the wide range of disease states in which inflammation represents a key component. These models include those that make the assumption that there is a unifying inflammatory response which can be applied to all inflammatory stimuli. In contrast, models of inflammation have been developed that are specific for certain stimuli (such as pathogens or mechanical damage), or that are tailored to specific tissue types. In addition, many models of specific diseases, such as tuberculosis or cancer, have inflammatory interactions embedded within them. These models cover a wide spectrum of spatiotemporal scales, from the rapid intracellular events that are involved in the cellular response to exogenous inflammatory signals through to population-wide responses to infectious agents. Rather than provide a comprehensive review, we present an illustrative review of the breadth and depth of models that incorporate inflammatory mechanisms.

Early Events, Leukocyte Responses to Bacteria

The arrival of leukocytes to a site of tissue damage or infection is central to the inflammatory response. Leukocytes express adhesion molecules on their cell surface that allow them to bind to damaged or activated endothelial cells that line the blood vessels and subsequently move across the vessel to enter the tissues. This is a highly regulated process that involves cooperative action of adhesion molecules and chemoattractant cytokines that are released in response to injury or infection (Ley *et al.*, 2007). Lauffenburger and Kennedy developed a series of models that capture a generic leukocyte's response to bacterial infection (Lauffenburger and Keller, 1979; Lauffenburger and Kennedy, 1981; Lauffenburger and Kennedy, 1983). These simple models of two or three variables, representing bacteria, leukocytes, chemoattractants, and venules at various tissue scales, have been used to investigate how variation in key parameters, such as leukocyte capacity for motility or phagocytosis of bacteria, affect the dynamics of the inflammatory response and the outcomes of an infection. They found that localized areas of high leukocyte concentration, reminiscent of granuloma formation, occur more readily when leukocyte chemotaxis is defective, where there is a low growth rate of bacteria, or where bacteria are resistant to destruction by leukocytes.

With the aim of providing insight into sepsis, a sustained inflammatory condition can affect multiple organs and ultimately lead to death. Vodovotz and coworkers have also developed models that capture the acute inflammatory response to bacteria. Their initial model (Kumar *et al.*, 2004) is homogeneous (ignoring spatial variations), incorporating bacteria and two pro-inflammatory mediators. Model outcomes are equated to the clearance of the pathogen or progression to a sustained infection. Further work (Reynolds *et al.*, 2006) incorporates a generic leukocyte, bacteria, tissue damage, and an anti-inflammatory mediator to investigate how the strength of the anti-inflammatory mediator can affect the progression to a sustained infection. They have modified and extended this work to various experimental and disease scenarios, including the inflammatory response to endotoxin administration (a component of the bacterial cell wall) in mice (Day *et al.*, 2006) and the simulation of the inflammatory response to an anthrax infection (Kumar *et al.*, 2008), where they inferred that the administration of antibiotics is useful only if administered early. Reviews of their work are given in Vodovotz (2006) and Vodovotz *et al.* (2008).

Smith *et al.* (2011) combine bacterial measurements from mice infected with *Streptococcus pneumoniae* with mathematical modeling to investigate the inflammatory response to bacterial infection in the lung. Their series of quantified spatially averaged models, of increasing biological complexity, were used to investigate which components of the inflammatory response (resident macrophages, neutrophils, and monocyte-derived macrophages) contribute most to the ability of the lung to recover fully from the disease, finding that alveolar macrophages are critical for a successful response.

Inflammatory Cytokines, TNF-Therapy

Tissue injury or infection is characterized by production and/or release of molecules that act as triggers of inflammation. These molecules have been termed damage-associated molecular patterns (DAMPs) that are released from disrupted cells (e.g., extracellular nucleotides and high mobility group box 1 protein) or pathogen-associated molecular patterns (PAMPs) associated with microbial pathogens (e.g., bacterial endotoxin, lipotechoic acid, and flagellin) (Tang *et al.*, 2012). Macrophages and other cell types are able to recognize these DAMPs and PAMPs and produce a variety of pro-inflammatory cytokines that act to control the initiation and development of the inflammatory response (Dunne and O'Neill, 2003). Some of the key cytokines produced include those that characterize the acute phase response, including interleukin (IL)-1, IL-6, and tumor necrosis factor α (TNF- α). These cytokines act to promote activation of endothelial cells and the recruitment of leukocytes together with activation of cellular defense mechanisms (coagulation regulation, complement activation, promotion of phagocytosis, and production of destructive enzymes) which limit microbial growth and facilitate microbial destruction. However, prolonged elevation of levels of these cytokines can be detrimental and is associated with cancer cachexia or development and progression of inflammatory disease (Mantovani *et al.*, 2008; Nathan, 2002; O'Shea *et al.*, 2002; Stoll *et al.*, 2002).

Seymour and Henderson (2001) have developed a mathematical model to explore the complex relationship between a population of monocytes and the key inflammatory cytokines IL-1, IL-10, and TNF- α . This work was extended (Jit *et al.*, 2005) to explore the effects of therapeutically blocking TNF- α . Anti-TNF- α therapy has shown significant benefits to patients with RA but not to those with a systemic inflammatory response (SIRS), even though it involves a similar cytokine network to RA and has TNF- α as a key factor in its pathology. Utilizing the known pharmacokinetics properties of three soluble TNF- α inhibitors (TNFR2, Etanercept, and Infliximab), Jit *et al.* demonstrated the effectiveness of the inhibitors in controlling concentrations of free TNF- α under the conditions of RA. They proposed that, in contrast, under the condition of SIRS, therapeutically sequestered TNF- α can act as a slow reservoir sabotaging the therapeutic strategy. Cytokine networks involved in RA have also been modeled by Baker *et al.* (2013) who considered the interactions between generic pro- and anti-inflammatory cytokines; their simple model of two variables displays a range of outcomes, including oscillatory behavior that is reminiscent of a remitting-relapsing disease state. They demonstrate anti-inflammatory responses to anti-cytokine therapy, finding that dose-regime (as well as dose-level) is important for a successful outcome.

The response of a cell to inflammatory mediators is dependent on intracellular protein interactions. Mathematical modeling of inflammation at the subcellular scale has centered around the transcription factor NF- κ B, a key regulator of cellular responses to pro-inflammatory mediators including IL-1 and TNF- α . Prolonged activation of NF- κ B activity has been implicated in the development of chronic inflammatory diseases as well as cancer (Philip *et al.*, 2004). A review of mathematical models focusing on NF- κ B signaling is given by Hoffman and coworkers who also produce models in this area (Cheong *et al.*, 2008). Cancer and tumors have been extensively modeled (Byrne (2010) for a review of these). C-Abl is a tyrosine kinase central to subcellular interactions that affects a neutrophil's ability to undergo apoptosis. Jackson and Radivoyevitch (2013) model c-Abl mediated neutrophil responses in response to pathogens and infections, they simulate various treatment strategies predicting that the efficacy of kinase inhibitors Seliciclib and imatinib are additive.

Tissue Damage and Wound Healing

The inflammatory events that occur in response to tissue damage generally resolve, stimulating the successful events downstream where tissue is repaired and remodeled. One readily accessible system to follow inflammation and tissue repair is in the skin, where the response to trauma (wound healing) is easily observable. In a wound, inflammatory events are followed closely by, and interact with, downstream events such as wound closure, remodeling of the extracellular matrix, and angiogenesis that are necessary for the successful repair of tissue (Baum and Arpey, 2005; Singer and Clark, 1999). Theoretical models have focused on these downstream events. Sherratt and Murray (1990, 1991) model epidermal cell migration in acute wounds that heal successfully and a review of both of their, and others, work in this area is provided by Sherratt and Dallon (2002).

While minor wounds generally repair quickly this process can fail, leading to development of a chronic open wound, for example, pressure sores and leg ulcers and patients with diabetes are particularly susceptible to wounds of this kind. The failure of wounds to heal quickly has been suggested to depend on the presence of inflammatory cells. Waugh and Sherratt (2006) present a model that centers on the presence of inflammatory cells in normal and diabetic wounds. Their model captures two distinct populations of macrophages (with either an 'inflammatory' or a 'repair' phenotype) and the mediator TGF- β . Macrophages are capable of phagocytosis of cellular and particulate material and can produce a wide range of pro- and anti-inflammatory cytokines. Heterogeneity within the macrophage populations present at inflamed sites, together with distinct differentiation and activation responses to the local tissue micro-environment (Davies *et al.*, 2013; Murray and Wynn, 2011), represents a pivotal factor in the development and ultimate resolution of inflammation. Waugh and Sherratt find that the balance between the populations of macrophages of an inflammatory and repair phenotype vary under diabetic (compared to normal) conditions, affecting the subsequent wound healing process. This work was subsequently extended (Waugh and Sherratt, 2007) so that investigations could be carried out on the effect of applying two commercially engineered skin substitutes to diabetic wounds. The model showed close agreement to data from clinical trials and elucidates some of the underlying mechanisms involved in treatment.

Marée *et al.* (2005) investigate which aspects of macrophage phagocytosis are altered under diabetic conditions, formulating a model that captures the ability of macrophages to activate, engulf, and digest a series of dead cells. The capacity of macrophages to clear cells that have undergone programmed cell death (apoptosis) through a process of engulfment and digestion (phagocytosis) is central to inflammation and one consequence of the failure to remove apoptotic cells may be perpetuation of the inflammatory process and the subsequent failure of downstream events. Marée *et al.* compared their model to *in-vitro* time-course experimental data on macrophages obtained from normal and diabetic-prone mice. They found that macrophages from diabetic-prone mice are slower in their rate of activation (the time taken to remove the first apoptotic cell) and their ability to engulf apoptotic cells, but not slower to digest them. Further work (Marée *et al.*, 2006) investigates the effect of slower rates of macrophage activation and engulfment on secondary necrosis of pancreatic B cells showing that the difference in kinetics between normal and non-obese diabetic-prone mice is large enough to trigger an escalating inflammatory response in the later population of mice. Childs *et al.* (2011) also developed a model that focused on the role of macrophages in the context of wound healing, producing a model that investigates macrophage phenotype. Their work demonstrated how local microenvironmental conditions can lead to macrophages switching from an inflammatory phenotype to one that promotes wound repair.

Inflammation and Progression to the Immune Response

The inflammatory (innate immune) and adaptive immune response are closely entwined with macrophages playing a key

role in linking the early inflammatory response to the later adaptive immune response.

Rudnev and Romanyukha (1995) developed a model that focuses on the early inflammatory response to an infection by *Staphylococcus aureus* pneumonia in the lung. The model captures the ability of the pathogen to cause damage to the lung as well as the recruitment of neutrophils and macrophages and their capacity for removal of the bacteria. This work was later modified (Romanyukha *et al.*, 2006) to incorporate the cells of the adaptive immune response (antigen presenting, T, and B cells). The model investigates the long-term immune defense against an infection, estimating the energy burden required to fight infection during periods of health and disease.

An infection by the bacterium *Mycobacterium tuberculosis* leads to not only an innate but also an adaptive immune response that results in disease clearance, latency, or active tuberculosis. Inflammatory cells, particularly macrophages, are central to this disease outcome, collecting at the site of infection to form a granuloma that ‘walls off’ the bacterial infection (Russell, 2011). With the ultimate aim of understanding the processes that lead to granuloma formation and the aspects of an infection that can lead to latency, Kirschner and coworkers developed a number of models of the inflammatory and adaptive immune systems response to *M. tuberculosis* utilizing a range of mathematical techniques applied at different biological scales. An initial spatially averaged model (Wigginton and Kirschner, 2001) characterized the cytokine and cellular (both macrophage and T cell) interactions central to an infection. Bacteria populations are tracked outside (extracellular) and inside infected macrophages. Simulations demonstrate disease outcomes of latency (a lack of extracellular bacteria), active tuberculosis, and reinfection with results compared to experimental data. They found that even if latency is achieved there may be tissue damage. This work was extended (Marino and Kirschner, 2004; Marino *et al.*, 2004) to include trafficking of cells between the lung and the lymph nodes finding that a delay in either dendritic cell migration to the lymph node or T cell trafficking to the site of infection can alter an outcome of latency to one of active tuberculosis. Further models (Gammack *et al.*, 2005; Segovia-Juarez *et al.*, 2004) incorporate spatial variations. Gammack *et al.* (2005) concentrated on the early inflammatory response, before any adaptive immune response develops. They utilized reaction-diffusion-type equations to investigate how the expansion and contraction of a granuloma, in response to an infection, depends on interactions between macrophages, bacteria (both external and internal to macrophages), and a chemoattractant with cells trafficking across the granuloma boundary and moving within it in response to the chemoattractant. It was found that a model with just an inflammatory cell component was able to simulate uncontrolled granuloma growth or clearance. However, establishment of a stable granuloma (equated to a latent form of tuberculosis) was found to require an adaptive immune response component. A further spatial model (Segovia-Juarez *et al.*, 2004), that incorporated both adaptive immune cells (T cells) and innate immune cells (macrophages), utilizes a discrete cellular automata approach that combines a continuous representation of generic chemokines with discrete agent representations of macrophages and T cells. This novel approach

predicts that key elements that control the growth of a granuloma are the arrival time of T cells, chemokine diffusion rates, and macrophage overcrowding.

Conclusions and Future Challenges

Mathematical and computational models have a long history in being applied to biological processes. They can provide a bridge between biological knowledge, hypothesis, and experimental data allowing the extraction of more information from experimental data than is possible by intuition alone. Inflammation, with its dynamic complex nature, is particularly challenging to study both experimentally as well as mathematically. In experimental models of inflammation, capturing the complex cellular dynamics is often limited by the methods of sampling/analysis. For example, in a mouse model of infection in the lung, it is often necessary to sacrifice animals at a small number of distinct time points to examine cellular recruitment and measure levels of inflammatory mediators. This approach can often yield limited information with which to estimate changes in cell composition during an inflammatory response. Although this difficulty has constrained validation of mathematical modeling of inflammation, the predictive value of such models affords an opportunity not only to design new experimental protocols that would specifically enable modeling predictions to be tested but direct experiments to those targets that are the most therapeutically interesting. Importantly, inflammation in response to diverse stimuli and under many different disease conditions has many universal properties and such commonalities can be captured in generic models that aid in the understanding of the key processes that can bring about a change in outcome.

Inflammation is dependent on mechanisms that occur over many time and space scales and the mathematical and computational models that we have described utilize a range of mathematical techniques applied across a wide range of these scales. They attempt to capture the inflammatory response under many different disease scenarios and cross-comparison between models could highlight some of the key unifying mechanisms behind the inflammatory response. Though one of the key challenges with mathematical modeling is to enable biological knowledge and experimental data to be integrated across disparate scales, such integration can help us elucidate what happens when the components of inflammation are perturbed, producing testable predictions and providing insights into potential therapeutic targets.

Glossary

Angiogenesis Growth of new microvessels from existing blood vessels.

Angiopoietin A set of proteins that modulate capillary quiescence, stability, and angiogenic activation.

Fibroblast growth factor (FGF) A member of a family of homologous soluble proteins that can induce the differentiation, mitosis, migration, and survival of a variety of responsive target cells and can trigger angiogenesis.

FGF receptor (FGFR) A cell surface transmembrane receptor tyrosine kinase that binds FGFs with high affinity initiating intracellular signal transduction.

Intracrine activity Function within a cell of a growth factor in the absence of secretion.

Intussusception Growth of new microvessels by longitudinal division of existing microvessels.

Juxtacrine activity Function of a membrane-anchored growth factor receptor on one cell by its membrane-anchored ligand on an adjacent cell.

Neuropilin (NRP) A pair of cell surface transmembrane vascular endothelial growth factor co-receptors that can form ternary complexes with vascular endothelial growth factors and their receptor tyrosine kinases.

Notch A member of a small set of juxtacrine morphogen receptors that when activated by binding membrane-anchored ligands on adjacent cells induces intracellular signal transduction leading to differentiated functions, which in vascular endothelial cells includes inhibition of the tip cell phenotype in angiogenic stalk cells.

Paracrine activity Function of a secreted growth factor on a nearby cell.

Pericyte A cell closely related to macrovascular smooth muscle cells (SMCs) that binds to the microvasculature including capillaries and contributes to their stabilization.

Platelet-derived growth factor (PDGF) A member of a set of homologous soluble dimeric proteins that can induce the

differentiation, mitosis, migration, and survival of multiple types of cells, notably including macrovascular SMCs and microvascular pericytes.

PDGF receptor (PDGFR) A cell surface transmembrane receptor tyrosine kinase that binds PDGFs with high affinity initiating intracellular signal transduction.

Sprouting angiogenesis Growth of new capillaries by budding and extension from existing microvessels.

Stalk cell A proliferative endothelial cell following the leading tip cell in a growing capillary sprout.

Tie A cell surface transmembrane receptor tyrosine kinase that binds angiopoietins with high affinity either initiating or inhibiting signal transduction.

Tip cell The leading migratory and invasive endothelial cell of a growing capillary sprout.

Vascular endothelial cell A type of cell usually forming a confluent non-thrombogenic monolayer lining the inside of the cardiovascular system and is the primary cellular component of capillaries.

Vascular endothelial growth factor (VEGF) A member of a set of homologous soluble dimeric angiogenic and lymphangiogenic proteins that can induce the differentiation, mitosis, migration, and survival of vascular and lymphatic endothelial cells.

Vasculogenesis Generation of the initial embryonic blood vessels by a process of differentiation and organization of vascular progenitor cells.

VEGF receptor (VEGFR) A cell surface transmembrane receptor tyrosine kinase found primarily on vascular and lymphatic endothelial cells that binds VEGFs with high affinity initiating intracellular signal transduction.

Wnt A member of a set of soluble paracrine morphogens that binds and activates its cell surface receptors to induce differentiation, migration, and mitotic signaling cascades in target cells leading to cell specification, such as the generation of mesodermal cells during gastrulation.

Vascular Evolution

The circulatory system has evolved in complex multicellular organisms to distribute oxygen, nutrients, and immune cells and to remove metabolic waste products including CO₂. Most invertebrates that are too large to depend on simple oxygen, nutrient, and waste diffusion, such as insects, have an open circulatory system in which blood flows freely within tissues. However a few large invertebrates such as cephalopods (e.g., squid, octopus, and nautilus) have a closed circulatory system in which peripheral blood is pumped through blood vessels lined by an acellular basement membrane. Although the growth of these vessels might utilize mechanisms that exhibit some similarities with vertebrate blood vessels, they

appear to be devoid of the luminal monolayer of vascular endothelial cells (ECs) that sit on a cross-linked glycoprotein basement membrane throughout the vertebrate circulatory system. These uniquely specialized cells apparently arose during the evolution of vertebrates and are central to the growth and function of their vascular systems (Munoz-Chapuli, 2011; Lammert and Axnick, 2012).

Developmental Vasculogenesis

The cardiovascular system is the first organ system that forms in vertebrate embryos and its proper development is critical for the growth of subsequently formed organs. Vertebrate

development initiates from the fertilized zygote, proceeding by rapid cell division to generate the spherical blastula, which then begins to remodel and differentiate during gastrulation forming the endodermal, mesodermal, and ectodermal germ layers. Formation of mesoderm is dependent on the combined influence of bone morphogenic protein-4 (BMP-4), which is a member of the large transforming growth factor- β family, fibroblast growth factor (FGF) -4 and -8, and wntless-int (Wnt). Intracellular signaling triggered by specific cell surface receptor binding of these and perhaps other soluble factors leads to the induction of the Brachyury and Tbx6 transcription factors required for mesoderm differentiation (Figure 1; Kimelman, 2006; Dorey and Amaya, 2010). FGF signaling through the FGF receptor-1 (FGFR1) supports development of the portion of the mesoderm destined to develop into the cardiovascular system (Yamaguchi *et al.*, 1994).

Figure 1 Developmental endothelial cell lineage. Early differentiation of the fertilized zygote generates a spherical blastula that remodels by gastrulation into the endodermal, mesodermal, and ectodermal germ layers. The secreted signaling proteins BMP, FGF, and Wnt induce the transcription factors Brachyury and Tbx6 that specify mesoderm, which is characterized by expression of the *fgfr1* gene and its activation by endogenous FGFs. Expression of the FOX-C2/E71 transcription factors differentiates a subset of mesodermal cells into hemato-cardiovascular progenitors characterized by expression of the vascular endothelial growth factor receptor-2 (*vegfr2*) gene. These cells can subsequently give rise to hemangioblasts, the progenitors of angioblasts that differentiate into vascular endothelial cells and hematopoietic stem cells that give rise to erythrocytes and multiple types of leukocytes. Alternatively, co-expression of the platelet-derived growth factor receptor- α (*PDGFR α*) gene generates cardiovascular progenitor cells that can differentiate either into cardiac muscle or into smooth muscle cells (SMCs) and pericytes. Therefore, cardiovascular development is dependent on FGFs, VEGFs, and PDGFs.

Although multiple transcription factors that might contribute to vascular differentiation are expressed under the control of BMP, FGF, and Wnt in vascular EC progenitors, a single transcription factor uniquely responsible for the developmental pathway has not been identified. Instead, the EC lineage appears to be critically dependent on cooperative binding and functional synergy between the transcription factors forkhead-C2 (FOX-C2) and ETS-related 71 (ER71, also known as ETV2) (Figure 1). These two proteins can form a heterodimeric complex on a highly conserved *cis*-acting FOX:ETS composite DNA-binding site, which is functionally restricted to the vascular EC lineage (De Val *et al.*, 2008; De Val and Black, 2009), and can transiently activate multiple EC-specific genes including *vegfr2* (often referenced as *flk1* in mice) encoding vascular endothelial growth factor receptor-2 (VEGFR2). The mesoderm-derived vascular EC lineage is dependent on the expression of VEGFR2, which is a cell surface transmembrane receptor tyrosine kinase that binds the extracellular soluble ligand vascular endothelial growth factor-A (VEGF-A). ER71/ETV2 appears in mesoderm by E7–7.5 followed by a rapid decline after E11.5 once ECs begin to mature. Mice lacking the *vegfr2* gene are defective in hematopoietic and vascular EC development and do not survive past embryonic stage E8.5–9.5 (Park *et al.*, 2013).

Subsequently, these cells can differentiate in a VEGF-dependent manner into (1) *vegfr2*⁺*PDGFR α* ⁺ (platelet-derived growth factor receptor- α) cardiovascular progenitor cells that differentiate into *vegfr2*⁺*PDGFR α* ⁺ cardiac and smooth muscle cells (SMCs), and (2) *vegfr2*⁺*PDGFR α* [−] hemangioblasts. The hemangioblasts give rise both (3) to hematopoietic stem cells, which are the precursors of multiple hematopoietic cell types including erythrocytes and leukocytes and (4) to the angioblast vascular EC progenitor that differentiates into mature ECs (Figure 1; Ishitobi *et al.*, 2011; Park *et al.*, 2013).

Vasculogenesis proceeds in both extraembryonic and embryonic tissues. In mouse embryos cells from both the lateral and posterior mesoderm migrate toward the extraembryonic yolk sac while aggregating into 'blood islands' at embryonic stage E6.5–7 containing cores of *vegfr2*[−] hematopoietic precursors that by E7.5 give rise to erythrocytes, surrounded by a shell of *vegfr2*⁺ angioblasts, which by E8.5 differentiate into ECs that assemble forming an extraembryonic capillary network. Simultaneously, within the embryo, angioblasts assemble into a capillary network and dorsal aorta in the absence of hematopoiesis. The extra- and intraembryonic vascular systems connect and upon initiation of a heartbeat and the flow of blood the capillary plexus remodels into an arterial, capillary, and venous circulatory system (Eichmann *et al.*, 2005). The function of the extraembryonic vascular system is to provide oxygen and nutrients and to remove metabolic by-products prior to the development of intraembryonic organs that eventually accomplish these critical functions. In addition, the parallel lymphatic system, necessary to drain blood vessel-derived extracellular fluid from tissues, develops from embryonic veins.

Following completion of embryonic vasculogenesis, growth of existing vessels can occur by the extensively studied mechanism of sprouting angiogenesis and by intussusception leading to longitudinal microvascular cleavage creating two smaller

daughter vessels. Although the molecular basis for intussusception is not clear, sprouting angiogenesis is induced by specific angiogenic protein growth factors.

Capillary Structure

Both sprouting angiogenesis and intussusception are mechanisms to generate new from existing capillaries. As illustrated in Figure 2, the structure of the existing capillaries is composed of a luminal monolayer of vascular ECs, which is continuous in most capillary beds. ECs sit on a thin (typically 50–100 nm) basement membrane consisting largely of collagen IV and to a lesser extent collagens XV and XVIII along with other proteins involved in cellular attachment but is devoid of lipid. The basement membrane is constructed by initial deposition of heterotrimeric laminin, a large helical coiled-coil cross-shaped protein that binds to specific cell surface components such as transmembrane integrins. Cell surface-anchored laminins assemble into a network that is indispensable for basement membrane formation. Nidogens (also called entactins) bind to laminin and to collagen IV, the principal collagen within basement membrane that then self assembles to form a fishnet arrangement that subsequently can be covalently cross-linked providing mechanical strength and stability to the capillary structure. Laminins also bind proteoglycans including perlecan that can themselves bind through their covalently linked negatively charged heparan sulfate oligosaccharide chains to a variety of proteins including several growth factors and their cell surface receptors (Iozzo, 2005; Eble and Niland, 2009). On the other side of the basement membrane and sometimes buried within it are pericytes, the microvascular counterpart of SMCs surrounding larger vessels, which form a non-confluent

Figure 2 Capillary structure. In most organs capillaries are composed a confluent monolayer of vascular endothelial cells (ECs) attached to each other (blue) and to the underlying basement membrane (black line) made of extracellular proteins that they express and secrete. Attached to the opposite side of the basement membrane and sometimes embedded within it are pericytes (magenta), the microvascular counterpart of SMCs that surround larger vessels. Focal direct contacts exist between the ECs and protrusions from the pericytes that penetrate the basement membrane. Although the illustrated capillary cross-section contains three ECs, lumen of the smallest capillaries, which are just large enough to pass an erythrocyte, can be generated by a single EC.

and sometimes sparse layer of support cells. Both ECs and pericytes can contribute to the synthesis and assembly of their common basement membrane. However, pericyte protrusions through holes in the basement membrane can insert into membrane invaginations on the EC surface. Pericytes and SMCs, both of which express α -SMC actin, are often simply called mural cells (Armulik *et al.*, 2011).

Primary Factors Controlling Angiogenesis

Before describing the mechanisms known to control and coordinate the angiogenic response, some background molecular biology and biochemistry of the major angiogenic growth and remodeling factors that are recognized to drive this process, along with their activities in ECs and associated mural cells, will be summarized to provide perspective on their functions.

Angiogenic Growth Factors

Vascular growth and development has been recognized for over a century to occur not only in normal tissue growth and repair but also in pathologic conditions such as inflammation, certain retinal diseases, and solid tumor growth (Ferrara, 2002). Specific members of the FGF and VEGF families drive sprouting angiogenesis *in vivo* and *ex vivo*. They appear to do this primarily as a result of their ability to bind and activate their receptor tyrosine kinase transmembrane receptors resulting in the stimulation of EC migration and mitosis, as will be described later in greater detail.

FGFs

FGF ligands

Several well-characterized FGFs, including FGF-1, -2, and -4, potently stimulate vascular EC migration, mitosis, and survival culminating in angiogenesis. They are members of a large homologous protein growth factor family consisting of 22 known mammalian members. Although FGFs are numbered 1 through 23, humans and mice are missing FGF-15 and FGF-19, respectively, and human FGF-19 appears to be the species ortholog of mouse FGF-15. FGFs are small (~15–30 kDa) soluble proteins that typically function as monomers. Various FGF family members can exhibit intracrine activity within cells and, upon secretion, autocrine self-stimulation, paracrine activity on nearby cells, circulating endocrine hormonal functions or some combination of one or more of these mechanisms.

FGF receptors

With the exception of FGF-11 through FGF-14, which are structurally homologous but not functionally similar, FGFs bind to one or more of four homologous high-affinity FGFR gene products, designated FGFR1-FGFR4. From the N- to C-terminus these transmembrane receptors each contain three extracellular immunoglobulin-like (Ig-like) domains, a single transmembrane spanning helix, an intracellular juxtamembrane region, a double domain 'split' intracellular tyrosine kinase containing a short 'kinase insert domain' sequence within its C-terminal folding domain, and a C-terminal tail (Figure 3). The FGF-binding site spans the second and third

Figure 3 Major capillary growth factor ligand, receptor, and co-receptor domain structures. The FGFR, VEGFR, PDGFR, Tie2 receptors, and the neuropilin (NRP) co-receptor each contain multiple extracellular domains (blue). Different extracellular domain folds are each denoted by a unique shape. The ligands (yellow) are docked to their extracellular receptor-binding domains. VEGF isoforms containing a positively charged C-terminal region bind the NRP co-receptor at a site spanning the $\beta 1$ and $\beta 2$ domains forming a VEGFR-VEGF-NRP complex. Each receptor/co-receptor spans the cellular plasma membrane (narrow yellow bar) via a single helical transmembrane (TM) polypeptide sequence (green rectangle). The four receptors each contain an intracellular juxtamembrane region (black line), double domain tyrosine kinase (TK) (red) that contains a kinase insert domain (not shown) and C-terminal tail (black line). NRP contains a relatively short, probably unstructured, intracellular sequence that is devoid of enzymatic activity but can bind specific signaling molecules.

extracellular Ig-like domains. Alternative splicing of the third coding exon, corresponding to the C-terminal half of the membrane proximal Ig-like domain 3, generates the IIIb and IIIc isoforms of FGFR1 – FGFR3 (Holzmann *et al.*, 2012). Therefore, alternative splicing generates seven major FGFR isoforms, each with a unique FGF ligand-binding site and selectivity pattern (Ornitz *et al.*, 1996; Zhang *et al.*, 2006). This creates a distinct receptor isoform recognition pattern for each FGF that partially overlaps the receptor recognition pattern of other FGFs resulting in redundant stimulation among some of the FGF family members. In addition, the biological activities of individual FGFs are restricted by the spatial and temporal pattern of their expression and that of their receptors, processes largely controlled by transcription factors that bind to their specific promoter and enhancer sites. The angiogenic FGF-1, -2, and -4 can each activate all of the FGFR1-FGFR3 IIIc isoforms (Ornitz *et al.*, 1996), which are expressed by vascular ECs (Antoine *et al.*, 2005), and stimulate the migration, mitosis, and survival of not only these cells but also a wide spectrum of other types of cells.

Heparin sulfate proteoglycan binding

Multiple paracrine FGFs, including those exhibiting angiogenic activity, bind to negatively charged heparan sulfate proteoglycans (HSPGs) such as syndecans, glypican, and perlecan present on cell surfaces or extracellular matrix (ECM) including basement membranes, albeit with approximately two orders of magnitude lower affinity than to the FGFRs. Binding to the high capacity cell surface HSPGs can increase the concentration of FGF in the vicinity of the FGFRs thereby possibly enhancing the apparent ligand–receptor affinity. In addition, HSPGs and the more highly sulfated soluble counterpart heparin sulfate (HS) can bind both FGF and FGFR to form a

ternary cell surface complex. ECM HSPG can also serve as a reservoir for heparin-binding FGFs that are released by mast cell-derived HS, heparanases, and proteases.

FGFR signaling

Signal transduction is best characterized for FGFR1, which is the major EC FGFR and triggers many of the activities associated with vascular EC FGF responsiveness. FGF binding is thought to promote FGFR dimerization bringing the intracellular tyrosine kinase domains into close proximity and proper orientation where they can cross-phosphorylate each other. The initial dimeric receptor subunit transphosphorylation occurs on a single tyrosine in the kinase enzyme activation loop that shifts the loop conformation, increasing accessibility to the active site and enhancing phosphotyrosine catalytic activity by approximately two orders of magnitude. The activated kinase then phosphorylates tyrosine residues in the juxtamembrane region, kinase insert, and C-terminal tail that serve as binding sites for proteins able to initiate activation of several signaling cascades mediated by sequential phosphorylation of proteins. The final step is phosphorylation of a second activation loop tyrosine residue that increases catalytic activity by another order of magnitude (Furdui *et al.*, 2006). The major substrates of FGFR tyrosine phosphorylation include the adaptor protein FGF receptor substrate 2 (FRS2) and the enzyme phospholipase $C\gamma$ (PLC γ). FRS2 triggers a cascade of signaling proteins leading to the activation of the extracellular signal-regulated kinase (Erk), which is a type of mitogen-activated protein kinase (MAPK) that migrates into the nucleus where it phosphorylates transcription factors controlling expression of specific genes involved in proliferation. In addition, FRS2 triggers the phosphoinositol 3-kinase (PI3K)-Akt pathway mediating cellular survival. The specific signaling

responses attributable to PLC γ include activation of protein kinase C (PKC) and translocation of the transcription factor 'nuclear factor of activated T-cells' (NFAT) into the nucleus stimulating cellular migration (Goetz and Mohammadi, 2013). In addition, FGF-2 can trigger EC HSPG syndecan-4 clustering, which via its short intracellular domain activates a PKC α -RhoG-Rac1 pathway; the GTPase Rac1 then promotes actin polymerization mediating migration (Elfenbein *et al.*, 2009). As appears to be the case for several growth factors, FGF/FGFR signaling, originally believed to happen at the plasma membrane, is now thought to occur predominately on intracellular endosomal vesicles (Zhang and Simons, 2014).

VEGFs

VEGF ligands

The mammalian VEGF family consists of five homologous gene products: VEGF-A, VEGF-B, VEGF-C, VEGF-D, and placental growth factor (PlGF), each of which forms functional homodimers. The best characterized angiogenic family member is VEGF-A (sometimes denoted simply as VEGF), which also exists as an active heterodimer with PlGF. Deletion of a single VEGF-A coding allele (i.e., *vegfa*^{-/+}) in mice is embryonically lethal with a severely disrupted vasculature demonstrating not only the presence but also the gene dose is critical for proper vascular development. The primary VEGF-A mRNA transcript, composed of eight coding exons, is subject to alternative splicing of exons six and seven that encode positively charged amino acid sequences near the C-terminus, which generates 121, 145, 165, and 189 amino acid subunit isoforms (the corresponding murine VEGF-A isoforms are each one amino acid shorter). These range from no HS/HSPG binding for VEGF-A₁₂₁ to increasingly tighter binding with greater positive charge of the longer splice insert regions. Differential HSPG binding contributes to VEGF-A isoform diffusion gradients, which impact its spatial range of action. Release of HSPG-bound VEGF isoforms can be achieved by partial proteolysis with either plasmin or matrix metalloproteinase (MMP). Considering the proteolytic remodeling associated with angiogenesis, this might be a physiologically relevant mechanism of mobilizing matrix-bound VEGFs (Ferrara, 2010; Vempati *et al.*, 2014).

VEGF receptors

VEGFs function by binding one or more of the three VEGF receptors VEGFR1, VEGFR2 (also known as KDR), and VEGFR3. These receptors are present on vascular and lymphatic ECs and a restricted range of non-ECs. Mouse homozygous deletion of each of these three genes is embryonically lethal exhibiting disrupted embryonic vascular development.

Each receptor subunit contains seven extracellular Ig-like domains, a single transmembrane spanning sequence, and a cytoplasmic juxtamembrane region, a split tyrosine kinase containing a kinase insert domain within its C-terminal folding domain and a C-terminal tail (Figure 3). Similar to FGF/FGFR, VEGFs bind VEGFRs through receptor Ig-like domains two and three promoting receptor dimerization and cross-phosphorylation of the two adjacent intracellular tyrosine kinase domains. VEGF binding promotes VEGFR homodimerization and, in the case of VEGFR2, heterodimerization with VEGFR1 and VEGFR3. In addition, Ig-like domains 4, 6,

and 7 bind HS/HSPG forming a ternary complex with VEGF/VEGFR. Naturally occurring soluble splice variants of VEGFR1 (sVEGFR1, also known as sFlt1) and VEGFR2 (sVEGFR2 or sKDR), which are missing either one or two membrane proximal Ig-like domains, the transmembrane spanning sequence and entire cytoplasmic region, function to sequester their cognate VEGF ligands and might also form inactive heterodimers with membrane-spanning VEGFRs (Albuquerque, 2013; Singh *et al.*, 2013; Thomas, 2013).

Neuropilin co-receptors

Co-receptors are generally defined as cell surface molecules that influence ligand-receptor activity but do not contain intrinsic catalytic activity. In addition to HS/HSPG, VEGFs and their complex with VEGFR can also associate with the co-receptors neuropilin (NRP) -1 and -2, homologous single-pass transmembrane proteins each containing five extracellular domains (α 1- α 2- β 1- β 2-c/MEM), a single-pass transmembrane spanning, probably helical, polypeptide and short intracellular sequence (Figure 3). VEGFR binds to the VEGF core (encoded by *veg* exons 2–5) whereas the NRP β 1- β 2 domains bind the C-terminal cationic tail (encoded by alternatively spliced *veg* exons 7 and 8) of VEGF ligands. NRPs also directly bind VEGFR and stabilize the ternary complex, which can be further stabilized by HS/HSPG interaction. NRP-1, preferentially expressed in capillaries and arteries, can bind isoforms of VEGF-A, VEGF-B, and PlGF and function as a co-receptor for VEGFR1 and VEGFR2. Although NRP-1 can bind VEGF-A₁₂₁, only the VEGF-A isoforms containing one or both of the positively charged C-terminal regions generated by alternative splicing can simultaneously bind NRP-1 and VEGFR2. NRP-1 promotes VEGFR2 phosphorylation, signaling, internalization into vesicles that recycle back to the cellular surface avoiding receptor degradation, and promotes EC migration and survival. In contrast, NRP-2, which is expressed in vascular capillary ECs, veins and lymphatic ECs, binds VEGF-A, VEGF-C, VEGF-D, and PlGF isoforms and can function as a co-receptor for VEGFR1, VEGFR2, and VEGFR3 promoting EC migration and survival. NRPs were initially identified as receptors for the semaphorin class 3 (Sema3) family of seven soluble proteins (Sema A-G) involved in axon guidance. Sema3A and Sema3F, preferentially signaling through NRP-1 and NRP-2, respectively, exhibit anti-angiogenic activity inferring a NRP-mediated VEGF antagonistic function (Favier *et al.*, 2006; Parker *et al.*, 2012; Koch, 2012; Plein *et al.*, 2014; Djordjevic and Driscoll, 2013).

VEGFR signaling

Reminiscent of FGFR activation, the transphosphorylation of two tyrosine residues in the activation loop of VEGFR2, which restricts substrate access to the catalytic site, shifts its position opening access to the active site and increasing catalytic efficiency. This probably also occurs for VEGFR3 but a single amino acid difference in the VEGFR1 activation loop along with a repressor sequence in the juxtamembrane region substantially decreases its catalytic activation making this an inefficient tyrosine kinase, which might account for its minimal mitogenic activity despite binding VEGF-A with an order of magnitude higher affinity than VEGFR2. Therefore, at least in some situations not only sVEGFR1 but also the membrane-spanning VEGFR1 receptor tyrosine kinase can sequester

VEGFs effectively preventing the activation of the more efficient VEGFR2 and VEGFR3 signaling. Ligand binding induces additional phosphorylation at several other exposed tyrosine residues in each VEGFR cytoplasmic region creating functional binding sites for proteins required to trigger activation of signal transduction pathways. VEGFR2 activates pathways utilizing the PLC γ -PKC-Raf-MEK-Erk, TSAd-Src and PI3K-Akt signaling cascades mediating proliferation, migration, and survival, respectively. In addition, vascular permeability is increased by Src-triggered destabilization of EC-EC junctions. VEGFR2 heterodimerization with either VEGFR1 or VEGFR3 can alter not only ligand affinity but also some of the receptor tyrosine phosphorylation sites that in turn modify the efficiency of different signal transduction pathways and their resulting biologic functions (Koch *et al.*, 2011; Koch and Claesson-Welsh, 2012; Domigan *et al.*, 2015).

As was previously mentioned for FGFR, signaling induced by VEGFR2 occurs primarily on endosomes following endocytosis. These intracellular vesicles can then either target the receptor for degradation or recycle it back to the plasma membrane in an actively regulated manner. Compartmentalization into different endosomal populations might influence not only the duration of signaling but also the relative strength of different signaling pathways (Zhang and Simons, 2014). Signaling efficiency and duration can also be enhanced by association of the VEGF/VEGFR complex with not only the NRP co-receptors but also the integrin β 1 subunit, CD63 tetraspanin (i.e., a member of a specific family of proteins that span the plasma membrane four times) and syndecan-1 transmembrane proteins (Domigan *et al.*, 2015).

In addition to these VEGF-dependent canonical pathways, unanticipated VEGF-independent noncanonical VEGFR signaling and activities have been identified. The carbohydrate-binding protein galectin-1 can bridge the glycoproteins VEGFR and NRP-1 through their covalently attached oligosaccharides. In the case of VEGFR2 this induces migration whereas VEGFR1 promotes permeability in the absence of VEGF. Similarly, the simultaneous binding of galectin-3 to the oligosaccharide chains of multiple cell surface VEGFRs appears to cluster, activate, and prolong signaling by inhibiting their internalization and degradation in a VEGF-independent manner. The BMP antagonist gremlin also unexpectedly was found to bind VEGFR2, activating its autophosphorylation and binding to the α v β 3 EC integrin. How important these noncanonical pathways are in normal development, growth, and tissue repair has not yet been well characterized (Domigan *et al.*, 2015).

Vascular Remodeling Factors

New immature capillaries formed in response to angiogenic growth factor stimulation are fragile and unstable. To form persistent structures they must be stabilized by remodeling both their interaction with each other and with their environment. This is induced by autocrine and paracrine signals triggered by remodeling and stabilizing growth factors.

Angiopoietins

Like the VEGFs, the angiopoietin (Ang, also abbreviated Angpt) growth factor system largely targets the vasculature, the

developmentally and structurally parallel lymphatic system, and some hematopoietic cell lineages. However, rather than directly inducing angiogenesis, the Ang ligands modulate microvascular plasticity and stability thereby either facilitating or inhibiting capillary growth.

Ang ligands

Mammals express three unique Ang gene products, designated Ang1, Ang2, and Ang4 in humans (Ang3 is the mouse ortholog of Ang4, which are sometimes grouped as Ang3/4). The Ang ligands are each composed of an N-terminal superclustering and coiled-coil domains (Figure 3) that mediate subunit assembly into dimers, tetramers, hexamers, and higher order oligomers, and a C-terminal fibrinogen domain that interacts with its receptors mediating their clustering and induction of intracellular signaling.

Ang receptors

Two homologous Ang receptors, Tie1 and Tie2, each consist of a large extracellular region containing multiple Ig-like, epidermal growth factor (EGF)-like and fibronectin III-like folding domains, a single-pass transmembrane spanning helical peptide and an intracellular juxtamembrane region, split tyrosine kinase containing a short kinase insert domain within its C-terminal folding domain, followed by a C-terminal tail as shown schematically in Figure 3. They are primarily expressed on vascular and lymphatic ECs and deletion of either receptor is embryonically lethal, exhibiting loss of vessel integrity with fluid leakage.

A high-affinity ligand selective for Tie1 has not been identified so it is considered to be an 'orphan' receptor. In contrast, Tie2 (also known as TEK) binds the Ang1 and Ang4 agonists and Ang2, which is a weak agonist that can effectively function as an antagonist by competing with Ang1 and Ang4 binding. Tie1 and Tie2 typically heterodimerize with each other in vascular ECs. Ang1 binding can dissociate the receptor heterodimer allowing formation of Tie2 dimers, functional tetramers and larger aggregates. Ang2 binds at essentially the same receptor site used by Ang1 but neither efficiently dissociates nor activates the Tie1-Tie2 receptor heterodimer. However, in the absence of Tie1, Ang2 can bind and activate Tie2 thus functioning as an agonist (Barton *et al.*, 2014).

Tie signaling

Ang1 is constitutively produced by pericytes and SMCs. Functioning as a tetramer or larger oligomer, Ang1-induced formation of Tie2 homo-tetrameric or high-order clusters promotes receptor tyrosine phosphorylation. Although like other tyrosine kinases the purified recombinant Tie2 kinase contains a tyrosine in the activation loop, which in the crystal structure of the unphosphorylated state adopted the active conformation, the nucleotide binding loop that binds the ATP phosphates is present in a self-inhibitory conformation and the C-terminal tail appears to partially occlude the peptide substrate-binding site. In addition, phosphorylation of a specific tyrosine in the kinase N-terminal domain, which is known to bind a phosphatase, inhibits, or perhaps rapidly reverses, kinase activation. Therefore, whatever the mechanism of kinase activation, it likely differs from other characterized tyrosine kinases (Shewchuk *et al.*, 2000).

In the absence of EC–EC contacts, Ang1 induces Tie2 clustering at the EC–ECM interface, activating the binding of ‘Downstream of kinase-R’ (Dok-R) to one of the phosphotyrosines in the C-terminal region and activating cell adhesion and migration (Saharinen *et al.*, 2008). However, in the presence of EC–EC contacts the Ang1/Tie2 complexes (but not Tie1) migrate to the cell–cell interfaces with the activation of the PI3K/Akt signaling pathway promoting EC survival and inhibiting vascular permeability. Although Ang4 is a Tie2 agonist, its activity in microvascular function has not been well characterized. In contrast, Ang2 effectively functions as an antagonist of Ang1 activity, inhibiting Tie2 activation and signaling resulting in capillary destabilization (Huang *et al.*, 2010; Jeltsch *et al.*, 2013).

Platelet-derived growth factors

The platelet-derived growth factor (PDGF) family and their receptors (PDGFRs) are structurally similar to the VEGF/VEGFR family, indicative of a common ancestral gene. In newly formed capillaries, EC-derived PDGF is important for pericyte recruitment.

PDGF ligands

Four mammalian PDGF genes exist encoding PDGF-A, -B, -C, and -D, which each homodimerize and in the case of PDGF-A and -B also form a heterodimer with each other. PDGF-B is expressed by vascular ECs and PDGF-B gene knockout mice die soon after birth exhibiting extensive pericyte deficiency and resulting microvascular aneurysms. PDGF-A and -B polypeptide sequences N-terminal of the central receptor-binding region are cleaved before secretion whereas those of PDGF-C and -D are secreted as latent forms that require extracellular proteolytic processing to become activated. The propeptides are thought to remain non-covalently associated with the core PDGF regions that bind receptor. In fact the propeptides bind the same PDGF loops that bind the receptors and must be removed prior to receptor recognition. PDGF-A and -B but not -C or -D also contain positively charged C-terminal extensions that bind HS/HSPGs partitioning them to cell surface and basement membrane HSPGs. Deletion of just the C-terminal positively charged tail motif leads to diminished microvascular pericyte association with a phenotype intermediate between wild-type and PDGF-B genetic deletion (Chen *et al.*, 2013; Andrae *et al.*, 2008).

PDGF receptors

Two PDGFR genes encode transmembrane proteins PDGFR α and PDGFR β , each containing five extracellular Ig-like domains, a single membrane-spanning helix, and an intracellular juxtamembrane region, split intracellular tyrosine kinase containing a long kinase insert domain region and a C-terminal extension (Figure 3). PDGF dimers bind to the second and third Ig-like PDGFR domains promoting receptor dimerization in a manner analogous to the previously described binding of FGFs and VEGFs to their receptors. The PDGFRs form $\alpha\alpha$, $\alpha\beta$, and $\beta\beta$ dimers, each able to bind a subset of PDGF dimers. PDGFR β is expressed on mesenchymal cells, especially vascular SMCs and microvascular pericytes (Chen *et al.*, 2013).

PDGFR signaling

PDGFR β dimerization promotes transphosphorylation and activation of the tyrosine kinase activity leading to subsequent phosphorylation of tyrosine residues, which recruit signaling proteins that activate several of the same cellular signaling cascades previously described for FGF and VEGF including the Ras/MAPK (Erk), PLC γ , and PI3K pathways triggering rapid cytoplasmic responses and nuclear transcription of specific genes required for their cellular proliferation, migration, and survival activities. Given the overlap of many of the same signaling pathways not only between PDGFR α and PDGFR β but also among other receptor tyrosine kinases such as FGFRs and VEGFRs, at least some of the biologic specificity observed with each of the growth factors is the result of their cellular and temporal expression patterns and those of their cognate receptors (Andrae *et al.*, 2008; Demoulin and Essagher, 2014).

FGF–VEGF–Ang–PDGF Networking

Interactions among FGFs, VEGFs, Angs, and PDGFs, necessary to coordinate successful angiogenic responses, can be achieved through a variety of potential mechanisms. In addition to possibly augmenting activation of common signal transduction pathways (Simons, 2004) these growth factors can modulate expression of other growth factors and their receptors.

FGF-2 and VEGF-A can synergistically promote angiogenesis *in vivo*. Although ECs express FGFRs, neutralizing VEGF-A antibodies inhibit FGF-2-induced EC proliferation in culture and angiogenesis *in vivo* by up to 90%. These results are consistent with the observed FGF-2-induced expression of endothelial and stromal cell VEGF-A and EC VEGFR2. In fact, lack of EC FGFR signaling results in unresponsiveness to VEGF, probably a consequence of basal VEGFR downregulation (Murakami and Simons, 2008; Murakami *et al.*, 2011).

FGF-2 and PDGF-BB also synergistically enhance angiogenesis. FGF-2 but not VEGF-A induces PDGFR α and PDGFR β receptors in endothelial and mural cells increasing the response of both types of cells to PDGF angiogenic stimulation. FGF-2 potently induces EC proliferation but only modestly stimulates migration whereas PDGF-BB induces migration but not proliferation so it bolsters the migratory activity of FGF-2 in these cells (Kano *et al.*, 2005; Zhang *et al.*, 2009). In mural cells FGF-2 is also reported to increase expression of PDGF-C, which can bind and activate PDGFR- $\alpha\alpha$ and - $\alpha\beta$ (Lee *et al.*, 2013). Therefore, the observed angiogenic activity of endogenous PDGF-CC and its receptors is facilitated by FGF-2.

FGF-2 and VEGF-A each can stimulate Ang2 expression. VEGF-A has also been found to promote rapid (30 min) and slow (24 h) cleavage of the Tie1 and Tie2 ectodomains, respectively, first increasing and subsequently decreasing the Tie1/Tie2 ratio. This receptor modulation would initially enhance Tie2-mediated EC stabilization but eventually diminish it, having the effect of dampening a response to transient exposure of VEGF but facilitating the response to chronic exposure (Singh *et al.*, 2012).

As summarized in Figure 4, the ability of FGF-2 (and probably the functionally related FGF-1 and FGF-4) to regulate

VEGF, PDGF, and Ang activities indicates that it might orchestrate the coordinated induction of angiogenic responses mediated by these other growth factors (Murakami and Simons, 2008).

Figure 4 FGF induction of angiogenic growth factors and their receptors. FGF-2 acting through one or more FGFRs can upregulate expression of Ang2 in ECs, PDGF-C in mural cells and VEGF-A in both ECs and stromal cells. VEGFR2 can also upregulate expression of Ang2. FGF-2 also induces expression of VEGFR2 in ECs and upregulates both PDGFR α and PDGFR β in ECs and mural cells. Therefore, FGF-2 appears to coordinately control the expression of several other growth factors and their receptors that participate in the induction of angiogenic responses. Black arrows indicate induction of expression; blue arrows denote ligand activation of their cognate receptors.

Hypoxic Induction of Angiogenesis

Angiogenesis is a primary compensatory response to decreased tissue oxygenation. Normal tissue oxygen levels vary within and among organs but typically fall in a range of 3–9%, substantially less than the 21% present in air. Within cells this is even lower, ranging from 1.3 to 2.5%. *In vitro*, extracellular pO_2 levels of 2% or less are commonly considered to be hypoxic. Below approximately 1% cellular ATP levels fall and apoptosis can be triggered (Carreau *et al.*, 2011).

Cells cope with hypoxic stress by increasing the transcription and translation of several proteins important for angiogenesis and erythropoiesis that promote tissue oxygenation and others, such as glycolytic enzymes, that allow cells to generate ATP under conditions of reduced O_2 availability, albeit much less efficiently than by oxidative phosphorylation. Hypoxia-responsive genes involved in angiogenesis include VEGF-A, PIGF, Ang2, and PDGF-B.

Hypoxic cells can sense low oxygen levels using hypoxia-inducible factor (HIF), an $\alpha\beta$ heterodimeric transcription factor composed of an oxygen labile α subunit and a stable β subunit. Under hypoxic conditions HIF-1 α migrates to the nucleus and forms a heterodimer with HIF-1 β that binds to a specific hypoxia response element (HRE) genomic promoter or enhancer sequence. As illustrated in Figure 5, the HIF

Figure 5 Hypoxia sensing mechanism. In hypoxic conditions hypoxia-inducible factor-1 α (HIF-1 α) migrates to the nucleus and forms a complex with HIF-1 β that binds the genomic hypoxia response element (HRE) DNA sequence. The HRE-bound HIF $\alpha\beta$ heterodimer binds the transcriptional coactivator p300/CBP that also binds and activates the basal transcriptional apparatus. This mechanism activates transcription of a set of HRE-containing genes that encode proteins involved in the metabolic and angiogenic response to hypoxia. In normoxic conditions HIF-1 α is rapidly inactivated by two O_2 -dependent mechanisms. Factor inhibiting HIF-1 (FIH-1) hydroxylates a specific HIF-1 asparagine residue, preventing its binding to the p300/CBP transcriptional coactivator. In addition, prolyl 4-hydroxylase domain (PHD) enzymes hydroxylate two specific HIF-1 α prolyl residues that allow the von Hippel–Lindau (VHL) ubiquitin ligase to polyubiquitinate it triggering proteasome degradation.

heterodimer also binds the p300/CBP (cAMP response element-binding protein) transcriptional coactivator proteins that bridge it to the basal transcription apparatus activating transcription. Two complementary mechanisms exist to prevent the transcription of hypoxia-responsive genes in normoxic conditions. The first is hydroxylation of a specific HIF-1 α asparagine residue by factor inhibiting HIF-1 (FIH-1) that prevents it from binding the p300/CBP coactivator needed to induce transcription. In the second mechanism prolyl 4-hydroxylase domain (PHD) proteins hydroxylate two proline residues on HIF-1 α marking it for ubiquitination by the von Hippel-Lindau (VHL) protein, a member of the E3 ubiquitin ligase complex, and rapid degradation in proteasomes. Below approximately 5% extracellular oxygen the catalytic rates of FIH-1 and PHD diminish as a function of oxygen substrate concentration becoming inactive in its absence so these enzymes serve as the primary oxygen detectors calibrating transcription of hypoxic response genes (Semenza, 2014; Walshe and D'Amore, 2008).

Most transcribed mRNAs are modified by the enzymatic addition of a guanine triphosphate linked through its 5' end to the 5' end of the nascent message, which is then methylated on the guanine seven position to form the m⁷GpppN 'cap' that is recognized by the ribosomal translational initiation cap-binding complex. However, as part of the cellular response to mitosis and to stress, such as severe hypoxia, most cap-dependent protein synthesis is inhibited, presumably to conserve energy. In contrast, the mRNAs encoding proteins important for responding to hypoxia, including those that can drive angiogenesis such as FGF-1, FGF-2, VEGF-A, and PDGF, are preferentially translated under hypoxic conditions. This may occur by use of an internal ribosome entry site (IRES), a stem-loop mRNA structure usually present in the 5' untranslated region upstream of the initiation codon that allows uncapped mRNA translation by one or more incompletely characterized mechanisms (Simon *et al.*, 2008; Komar and Hatzoglou, 2011; Majmundar *et al.*, 2010).

Sprouting Angiogenesis

After completion of early embryonic vasculogenesis most new capillaries appear to be formed by a process of sprouting from the existing microvasculature, especially capillaries, as shown schematically in Figure 6. This process involves a series of steps including initial dissociation of stabilizing pericytes, loosening of inter-EC junctions and degradation of the capillary basement membrane, followed by vascular EC migration, mitosis, tube formation, and fusion culminating in recruitment of pericytes and deposition of basement membrane required to stabilize the new capillary.

ECM Proteolysis

Sprouting angiogenesis is initiated by the binding of angiogenic proteins such as FGFs and VEGFs to their EC-specific plasma membrane receptors. One of the earliest effects of receptor binding and stimulation is the activation of the proenzyme forms of MMPs and serine proteases.

Figure 6 Sprouting angiogenesis. In response to an angiogenic stimulus such as VEGF microvascular ECs proteolytically degrade their basement membrane and migrate away from the parental vessel. The leading tip cell (TC)(red) extends long filopodia containing VEGFRs that allow it to sense and chemotactically migrate up a VEGF gradient. The TC secretes PDGF, which attracts pericytes (magenta), and basement membrane (black line) components onto which the following stalk cells (green) migrate and proliferate allowing the stalk to extend. A narrow slit opens between adjacent stalk cells that can continue to expand into a capillary lumen large enough to accommodate erythrocytes (red ellipses). As the stalk grows ECs near its base become quiescent phalanx cells (blue). A capillary sprout can fuse at its tip either with another sprout to form a continuous linear capillary lumen or with an existing capillary to generate a microvascular branch capable of supporting blood flow.

EC membrane-type 1 MMP (MT1-MMP) is activated intracellularly and exported to the pericellular side of the plasma membrane. Within approximately 30 min of angiogenic growth factor receptor binding a PI3K signaling pathway-dependent activation of MMP-2 occurs that in turn activates urokinase plasminogen activator (uPA), a serine protease that converts inactive plasminogen proenzyme to an active plasmin protease. Plasmin can also activate MMPs including MMP-9, which can degrade the basement membrane collagen IV scaffold. These proteases, along with others that they activate, degrade the constraining capillary basement membrane and ECM. MT1-MMP and uPA/uPA receptor cluster at the leading edge of migrating ECs contributing to their ability to penetrate and move through extracellular matrices (Van Hinsbergh *et al.*, 2006; Breuss and Uhrin, 2012).

Destabilization of EC-EC Junctions

Intercellular junctions between ECs, mediated by adherens junctions and tight junctions, stabilize the vascular endothelial monolayer. These junctions need to be destabilized to allow sprouting ECs to migrate from existing microvessels in response to angiogenic inducers. ECs uniquely express the adherens junction transmembrane protein vascular endothelial-cadherin (VE-cadherin), which contains five extracellular Ig-like domains, a single-pass transmembrane helical sequence and C-terminal intracellular region. VE-cadherins from adjacent ECs are thought to form a zipper-like structure between them. Although the VE-cadherin crystal structure shows overlap between the N-terminal Ig-like domains on VE-cadherins from opposing directions, they are also thought to

Figure 7 Endothelial junction structure and destabilization. Two types of endothelial cell junctions have been identified, both of which link transmembrane intercellular adhesion proteins to the intracellular actin cytoskeleton. Mutual binding of the N-terminal Ig-like domains of VE-cadherin molecules (blue) from adjacent ECs can create an adherens junction (top) and greater overlap among the Ig-like domains might be able to stabilize narrower junctions (center). The VE-cadherin intracellular domain binds p120 (green) and β -catenin (red), which is linked to actin (yellow) by α -catenin (purple). Narrower tight junctions (bottom) are formed by occludin (dark blue) and claudin (orange), two types of integral membrane proteins, each of which probably multimerizes and forms long ribbons that prevent diffusion of all but small molecules between ECs. VEGFR-activated signaling pathways can induce phosphorylation of VE-cadherin, β -catenin, occludin, and claudin destabilizing both adherens and tight junctions to induce vascular permeability and mobility.

be able to generate narrower adherens junctions by overlapping multiple Ig-like domains as illustrated in [Figure 7](#). VE-cadherin binds near the membrane to p120 that influences VE-cadherin retention and spatial organization at the cell surface. The C-terminal tail of VE-cadherin binds β -catenin that in turn binds α -catenin, which attaches to actin thereby linking cell surface intercellular junctions to intracellular cytoskeleton microfilaments ([Bravi et al., 2014](#)).

EC tight junctions, also illustrated in [Figure 7](#), are interspersed with adherens junctions but are thought to be more prevalent near the apical (luminal) surface. They limit passage of molecules through the EC–EC contact interface to approximately 800 Da. Tight junctions are composed of linear strands consisting of multiple proteins including occludins, EC-specific claudin-5, junctional adhesion molecules (JAMs), and zona occludens-1 (ZO-1), which links it to the actin cytoskeleton. VE-cadherin/ β -catenin, acting through the PI3K/Akt pathway, expels a claudin-5 transcriptional repressor from the nucleus, effectively upregulating claudin-5 transcription and facilitating EC tight junction formation ([Bravi et al., 2014](#)).

The stability of the intercellular junctions is controlled by phosphorylation. VEGFR2, acting through endothelial nitric oxide synthase (eNOS) generation of nitric oxide, can

nitrosylate β -catenin promoting its dissociation from VE-cadherin. VEGFR2-activated signaling pathways also phosphorylate VE-cadherin tyrosines in the binding sites for p120 and β -catenin, inhibiting adherens junction complex formation and promoting the internalization and degradation of VE-cadherin. Either the same or a different pool of β -catenin migrates to the nucleus and interacts with additional transcription factors to downregulate expression of the tight junction protein claudin-5. VEGF also induces serine phosphorylation of occludin, which increases ubiquitination that marks it for proteasome degradation. In addition to destabilizing EC intercellular junctions, growth factor-induced Rho GTPase activity promotes actin cytoskeleton contraction-mediated opening of the gaps between ECs. In contrast, Ang1-activated Tie2 signaling can inhibit VEGF-mediated EC junction destabilization, a process that can be functionally inhibited by the Tie2 weak agonist Ang2 ([Goddard and Iruela-Arispe, 2013](#); [Bravi et al., 2014](#)). Therefore, as denoted in [Figure 7](#), VEGF-induced destabilization of both adherens and tight junctions not only increases vascular permeability but also inhibits intercellular adhesion facilitating EC migration.

Dissociation of Pericytes

In stable vessels pericytes and in larger vessels SMCs constitutively express Ang1, which binds and activates EC Tie2 receptors. Tie2 intracellular signaling in ECs promotes cell survival and vessel stabilization by activation of PI3K, which leads to Akt-mediated inhibition of apoptosis, and Rho GTPase-induced stabilization of adhesion junctions between ECs. In response to hypoxia and to VEGF, ECs upregulate and release Ang2 from their Weibel–Palade storage granules. This inhibits the Ang1-mediated EC quiescence, facilitating angiogenic remodeling with dissociation of stabilizing pericytes from the capillary ([Augustin et al., 2009](#)). ECs and pericytes can form a common adherens junction that utilizes N-cadherin rather than the VE-cadherin found in EC–EC adherens junctions ([Gaengel et al., 2009](#)). Possibly some of the same or similar pathways that trigger VE-cadherin destabilization can also disassemble these N-cadherin adherens junctions.

Migration and Proliferation

Once the intercellular adhesive and matrix barriers are removed ECs can migrate from an existing microvessel to form a new capillary shoot. This is accomplished by an organized process in which a single cell, called a ‘tip cell’ (TC), shown in [Figure 6](#), exhibits a migratory but minimally proliferative phenotype. The initial induction of this TC phenotype is mediated by VEGF and possibly biased toward selection of the first available cell released from its intercellular junction and matrix constraints. Soluble VEGFR1 (sVEGFR1/sFlt1) is produced by the parental vessel ECs near the sprout base. By sequestering VEGF on either side of the sprout sVEGFR1 creates a perpendicular corridor of VEGF that keep the sprout growing away from the parental vessel ([Chappell et al., 2012](#)). In response to VEGF TCs extend multiple thin extensions called filopodia that incorporate VEGFR2 and VEGFR3, at least some of which function as VEGFR2/3 heterodimers, allowing them

to sense and migrate up a VEGF chemotactic gradient. Receptors for other guidance signals on TC filopodia can also sample the local environment, detecting other attractive or repulsive ligands that promote filopodia extension or retraction, respectively, thereby controlling directional migration in a manner analogous to axonal growth cones (Potente *et al.*, 2011; Michaelis, 2014; Jeltsch *et al.*, 2013).

The migrating TC is followed by a column of ECs denoted as stalk cells as illustrated in Figure 6 that elaborate few, if any, filopodia but are proliferative so can elongate the growing capillary stalk. Tip and stalk cell phenotypes are maintained by mutual cross-modulation of their Notch signaling systems. By virtue of being exposed to the highest gradient concentration of VEGF, TCs express decreased levels of the Notch transmembrane receptor and elevated levels of its transmembrane delta-like 4 (Dll4) ligand. TC Dll4 binds and activates Notch in adjacent stalk cells as shown in Figure 8. On activation the Notch intracellular domain (NICD) is liberated by limited proteolysis and migrates to the nucleus where it downregulates VEGFR2 and VEGFR3 and also upregulates VEGFR1, which binds VEGF with a higher affinity, effectively sequestering it to prevent additional TC generation and to maintain the highest chemotactic VEGF gradient concentration ahead of the TC. A second membrane-anchored Notch ligand, Jag1, is expressed by stalk cells and functions as a weak agonist, which decreases TC Notch signaling by competing with the stronger Dll4 agonist. Therefore, by this mutual 'juxtacrine' signaling between adjacent TCs and stalk cells Notch signaling is increased in stalk cells but decreased in TCs.

The unique phenotype of a TC is actively maintained but transient. The TC phenotype half-life has been measured to be approximately 4 h *in vivo*, after which it reverts to being a stalk cell and is replaced by another stalk cell that becomes a TC (Carmeliet and Jain, 2011; Potente *et al.*, 2011; Ribatti and Crivellato, 2012).

Sprout Lumen Formation

Several alternative mechanisms of lumen formation have been proposed including (1) extension from an existing lumen, (2) fusion of vacuoles within single ECs that then fuse in a sequence of ECs along the sprout, and (3) formation of a slit between laterally adjacent stalk cells followed by expansion to create an open lumen. Although any or all of these mechanisms might contribute to lumen formation, the process appears to be driven primarily by the third alternative. The initial step in this process is generated by migration of adherens and tight junctions between ECs toward the basal (outside) edge of the sprout cord EC-EC interfaces and exocytotic insertion of membrane-anchored protein sialomucins including podocalyxin (PODXL) into the juxtaposed plasma membranes as illustrated in Figure 9(a). The highly negatively charged sialomucin oligosaccharides repel the adjacent EC plasma membranes creating an open slit between them, shown in Figure 9(b). The slit is subsequently expanded into a lumen by redistribution of moesin to the apical (luminal) membrane, where after being phosphorylated by PKC it links PODXL to F-actin. In addition, VEGF signaling activates Rho-associated coiled-coil kinase (ROCK) and phosphorylation of non-

Figure 8 Tip-stalk cell signaling. Tip cells (TCs) (light red) express VEGFR2 and VEGFR3 homodimers along with VEGFR2/3 heterodimers, each of which can differentially activate intracellular signaling cascades leading to an invasive migratory phenotype. In addition, TCs express NRP VEGFR co-receptors and the membrane-anchored juxtacrine ligand Dll4, which binds its Notch receptor on adjacent stalk cells (green). This triggers proteolytic release of the Notch intracellular domain (NICD) that functions as a transcription factor increasing expression of VEGFR1 and Jag1 and downregulating VEGFR2 and VEGFR3 expression. Stalk cell membrane-bound and soluble VEGFR1 can sequester VEGF effectively diminishing its stimulation. Notch-induced Jag1 expression by stalk cells inhibits Dll4 activation of TC Notch, preventing NICD formation and downregulation of the genes that support the TC phenotype. This mutual juxtacrine signaling establishes a phenotypic difference between the leading TC and following stalk cells.

muscle myosin-II facilitating interaction with F-actin forming an actomyosin complex that generates the force required to retract the EC creating a fully open lumen, which is illustrated in Figure 9(c). The vessel and lumen diameter can subsequently grow by vacuole fusion and EC proliferation to create larger microvessels (Herbert and Stainier, 2011; Lamert and Axnick, 2012; Siekmann *et al.*, 2013).

Sprout Fusion and Flow

Functional microvascular loops can form by the fusion of two capillary sprouts. TC filopodia from each sprout contact each other and based on co-localization of VE-cadherin and ZO-1 likely form both stabilizing adherens and tight junctions. Macrophages can help stabilize the nascent junction but are

Figure 9 Lumen formation. (a) Activation of $\beta 1$ -containing integrins on a pair of adjacent stalk cells (green) induces PAR3-mediated migration of adherens junctions (AJs) and tight junctions (TJs) to the outer edge of the cellular interface. (b) Membrane-anchored highly negatively charged sialomucin proteins including PODXL are inserted into the adjacent EC plasma membranes creating charge repulsion that separates them. PKC-phosphorylated moesin (P-moesin, red circles) binds to the intracellular region of PODXL linking it to actin (straight black lines), which expands the opening. (c) Additional lumen expansion is mediated by contraction of actomyosin generated by expression of myosin that binds actin (parallel black lines between P-moesin and the cellular outer membrane) and fusion of vacuoles (open circles) with the open lumen.

not required. As the interface between the two juxtaposed TC membranes increases area they generate a luminal segment that can fuse with the advancing lumen from each sprout to form a continuous open capillary loop. Although branching can occur by sprout splitting it can also be generated by fusion of a sprout tip with an existing capillary (Siekman *et al.*, 2013; Lenard *et al.*, 2013). Once a continuous lumen is formed blood flow can commence, increasing oxygen delivery and downregulating hypoxia-induced transcriptional and translational expression of angiogenic mediators.

Vessel Stabilization and Maturation

Newly formed vessels are stabilized by basement membrane and pericytes. Deposition of basement membrane between ECs and pericytes contributes to the stability of newly formed capillaries by providing: (1) mechanical strength generated by

collagen IV covalent crosslinking, (2) integrin cell attachment ligands, and (3) a growth factor binding, storage, and presentation matrix. PDGF-BB expressed by ECs can bind HSPGs, presumably maintaining locally elevated concentrations that help recruit and retain pericytes by activating their PDGFR β receptors. Deletion of either the *Pdgfb* or *Pdgfr β* gene produces pericyte deficiency, microaneurysms, and bleeding demonstrating the critical need for pericyte microvascular stabilization. Pericytes in turn express Ang1 and activate EC Tie2 receptors stabilizing EC-EC junctions that inhibit vascular permeability. Therefore, EC PDGF-BB and pericyte Ang1 each function in a mutually paracrine manner to stabilize microvascular structure (Gaengel *et al.*, 2009). In addition, pericytes secrete the ECM protein vitronectin that can bind to the αv subunit of the EC integrin $\alpha v \beta 3$, upregulating EC expression of VEGF that functions in an intracellular or 'intracrine' manner binding to cytoplasmic VEGFR2 within the same cell, promoting expression of the anti-apoptotic Bcl protein to support EC survival and homeostasis (Domigan *et al.*, 2015).

FGFs not only induce angiogenesis but at low concentration support basal receptor signaling required for vascular stability. This appears to be accomplished by FGFR-mediated stabilization of the VE-cadherin/p120 catenin adherens junction complex mediated by the SHP2 phosphatase, which can reduce VE-cadherin phosphorylation-induced dissociation of p120 catenin (Goddard and Iruela-Arispe, 2013).

During vessel maturation the lipid sphingosine-1-phosphate (S1P), present primarily bound to blood-borne high-density lipoprotein (HDL) and albumin, functions to stabilize patent vessels. Acting through its three cell surface G-protein-coupled receptors on ECs, S1P stimulates the Rho family GTPases (Rac, Rho, and Cdc42) that regulate the actin cytoskeleton and EC barrier function. In particular, S1P activation of the S1P₁ receptor mediates Rac activation, promoting accumulation of VE-cadherin and β -catenin at cell-cell interfaces and strengthens both EC-EC VE-cadherin and EC-pericyte N-cadherin adherens junction assembly, thereby inhibiting angiogenic sprouting (Wietecha *et al.*, 2013; Xiong and Hla, 2014; Goddard and Iruela-Arispe, 2013).

Vessel Pruning

Angiogenic stimuli can induce numerous capillaries, some of which are either redundant or not positioned in the microvascular bed to achieve adequate blood flow. After hypoxic tissue becomes fully oxygenated by angiogenic expansion of the microvascular bed the survival of fully functional vessels exhibiting nonturbulent laminar flow shear stress is enhanced. The mechanism by which laminar flow sustains vessels is not entirely established but appears to involve activation of the PI3K/Akt pathway in ECs, which increases nitric oxide synthase and its product nitric oxide that can S-nitrosylate the active site cysteine in caspases, inactivating these proteolytic mediators of apoptosis. In contrast, capillaries in well-oxygenated environments that are inefficiently positioned in the microvascular bed to establish and sustain nonturbulent blood flow, do not efficiently activate this pathway and are more susceptible to apoptosis (Dimmeler and Zeiher, 2000), which promotes the destabilization and regression of these

less efficient vessels. In an analogous manner, retinal ECs exposed to hyperoxia then returned to normoxia, a procedure that causes retinal microvascular pruning *in vivo*, express FGD5, a guanine exchange factor protein that activates Cdc42 GTPase. Cdc42 induces Notch target genes resulting in downregulation of VEGFR2 and upregulation of VEGFR1 expression as occurs in stalk cells during sprouting, presumably sequestering VEGF, resulting in diminished survival signaling, p53 induction of apoptosis, and vessel regression (Wietecha *et al.*, 2013). In the absence of an angiogenic signal such as VEGF, Ang2 can also promote capillary destabilization and regression (Huang *et al.*, 2010; Jeltsch *et al.*, 2013). The net effect of microvascular pruning is to eliminate redundant and poorly functioning vessels, thereby optimizing efficient flow.

Intussusceptive Angiogenesis

Although sprouting has been the focus of most angiogenesis studies, an alternative method of capillary growth is longitudinal splitting or intussusception of existing microvessels that has been observed to occur in rapid developmental organ growth and the muscular response to exercise. Descriptive studies have indicated that the process begins with circumferential enlargement of preexisting microvessels exhibiting robust flow. This increase in diameter is accompanied by corresponding decrease in EC thickness with little or no proliferation and is followed by formation of a narrow (<5 μm) cylindrical pillar of tissue across the lumen that can consist of multiple ECs invaded by a core of pericytes or myofibroblasts as shown in Figure 10. Pillar formation is thought to be initiated by creation of a contact zone between opposing microvascular walls, perhaps assisted by adjacent cells such as pericytes. Additional pillars can form in sequence downstream from existing pillars. The luminal pillars can each grow in diameter culminating in their fusion to create a pair of internal EC walls extending down the axis of the vessel that allow it to split into two parallel daughter vessel branches. Intussusception is capable of rapidly expanding a microvascular network with little or no EC proliferation. It can also remodel an existing vascular plexus by either creating new vascular branches or by walling off and pruning existing branches (Makanya *et al.*, 2009).

Intussusception might reflect a modification of sprouting in which 'tip' ECs grow into the lumen instead of moving in the opposite direction into surrounding tissue. This is consistent with the lack of basement membrane and ECM proteolytic degradation in intussusception. The initiating stimulus for intussusception is unknown but might be triggered in ECs by hemodynamic forces within the vessels. Circulating angiogenic and remodeling factors such as FGF-2, VEGF, PDGF-B, and Tie2 also have been implicated. In particular, targeted Tie2 genetic deletion is associated with decreased pillar formation. However, to date, details of the molecular mechanisms that trigger and support intussusceptive angiogenesis remain essentially uncharacterized (Mentzer and Konerding, 2014).

Arterial and Venous Vessels

Although angiogenesis is a microvascular growth process blood flow into and from the capillaries is provided by small arterioles

Figure 10 Intussusceptive angiogenesis pillar formation. On the basis of microscopic observations intussusception appears to be initiated by formation of pillars that span the capillary lumen. This process is initiated in (a) an existing capillary by (b) EC surface expansion with decreased thickness allowing an existing vessel diameter to increase rapidly without proliferation. (c) EC surface depressions form, probably facilitated by pericytes or perhaps myofibroblasts, on one or both sides of the vessel leading to (d) deep invaginations. (e) As the two membranes meet they create a tunnel or pillar typically seen to be occupied by a pericyte or myofibroblast. In intussusceptive angiogenesis pillars commonly form in rows along the capillary, grow and fuse to create a pair of plasma membranes partitioning a lumen into two halves that then separate to form a branched pair of capillaries.

and venules, which in turn are supplied by larger arteries and veins. The fate of arterial and venous ECs is established in early embryogenesis by expression of the transmembrane EphrinB2 ligand and its EphB4 receptor tyrosine kinase. During vasculogenesis angioblasts expressing either EphB4 or EphrinB2 are each incorporated into the dorsal aorta but the EphB4-expressing cells subsequently migrate to form the cardinal vein.

In adults, arterial, arteriole, and capillary ECs express EphrinB2 whereas veins and venules predominately express EphB4, consistent with the early developmental segregation of expression. However, the expression of EphrinB2 and EphB4 overlap in several vessels. In addition, pericytes and SMCs express EphrinB2 and EphB4, which can promote and stabilize their normal attachment to ECs (Salvucci and Tosato, 2012).

Arterial development also is mediated by Notch activation of the HEY transcription factor signaling (Park *et al.*, 2013). In addition, as previously described, the VEGFR co-receptors NRP-1 and NRP-2 are asymmetrically distributed between arterial and venous ECs, respectively, although the significance of this distribution is not yet clear.

Summary

The characterization of angiogenic cellular responses and elaboration of some of their underlying genetic and biochemical mechanisms has advanced rapidly over the past few decades with the identification and characterization of the extra- and intra-cellular signals that trigger, coordinate and terminate the growth of blood vessels. The progress described in this article has been made possible by the development and application of new genetic, biochemical, cellular, and whole animal approaches that have been used to dissect the intricate control networks coordinating this multicellular physiologic response. Nevertheless, our understanding of this fundamental biological process remains incomplete and will likely continue to be a major focus of research in vascular cell biology for the foreseeable future.

A Review on Various Mathematical Modeling Approaches for Wound Healing

FJ Vermolen, Delft University of Technology, Delft, The Netherlands

© 2016 Elsevier Inc. All rights reserved.

Wound Healing and the Need for Modeling

Healing of damaged tissue is crucially important for the functionality of organs, survival, and well-being of humans and animals. To heal skin on which a wound has been inflicted a chain of many biological processes is initiated, of which the sequence and intensity is well orchestrated by the physiological system. Important processes are regeneration of extracellular matrix, the proliferation of constituent cells, such as fibroblasts in the case of skin wounds (burns and cutaneous wounds), cell death, clearance of polluting agents, engulfment of pathogens, and migration of cells. This migration is characteristic for the constituent cells and for the immune cells that hunt possible pathogens. This cellular migration is triggered by the physical environment that is experienced by the cell or the group of cells. From a medical perspective, the processes are characterized by the following sequence of partly overlapping consecutive phases: hemostasis, the proliferative phase, and the remodeling phase. During the hemostatic phase of cutaneous wounds, blood platelets originating, present from bleeding, regenerate a polymeric connective tissue state based on clotting that effectively seals of the damaged region, thereby effectively sealing off the wounded area. This temporary phase of connective tissue prevents the ingress of hazardous chemicals and pathogens and is hence indispensable for the survival of the organism. Next to the regeneration of connective tissue, the platelets release signaling cytokines that trigger the immune cells like macrophages to enter the wound area. These immune cells will clear up pathogens and hazardous chemicals and, in turn, release chemokines that initiate further cellular processes that take place in the proliferative phase. These processes are wound contraction, wound closure, and wound angiogenesis. On a fundamental biological level, cellular processes like migration and division (proliferation) are evoked. Wound angiogenesis is responsible for the revascularization of the damaged region if a deeper wound (in the sense that the dermis is wounded) is inflicted. This revascularization is necessary for the supply of oxygen and nutrients that are of vital importance to the constituent cells as well as for the functionality of the immune system in case of future wound healing and to clear up virally infected cells, detrimental bacteria, and mutated cells in the vicinity to prevent initiation of cancer. The (intermediate) contraction that is commonly observed in the deeper wounds is a survival mechanism to decrease the area of the wound exposed to the surrounded. Although this mechanism is highly favorable in cutaneous wounds, this mechanism is very undesirable in burns since severe contractions lead to contractures, which decrease the patient mobility, and possibly coexist with hypertrophic scars, which poses esthetic problems to the patient. The first two phases typically last in the order of several hours and several days, respectively. The final remodeling phase typically lasts several months up to several years or even remains uncompleted during the life span of the organism or patient.

The importance of wound healing, and wound prevention in cases where patients who are hospitalized over a long period and become sensitive to pressure ulcers, has given rise to several medical treatments with huge differences. These treatments range from the attachment of honey, which has been evidenced to inhibit progression of infection mechanisms into the wound region to stitching large wounds or even applying plastic surgery. In order to improve therapies, it is important to reveal the biological mechanism that underlies wound healing. To unravel these mechanisms, experimental data both *in vitro* and *in vivo* experimental data along with clinical observations are needed. Although the availability of these data is a necessary condition for the development of insight into the biology of wound healing, it is not yet sufficient for this understanding. To gain more understanding it is also necessary to develop theory on the basis of sound hypotheses. In order to validate biological hypotheses with experimental results, which merely are characterized by quantitative numbers, the quantification of the biological theory is necessary. This means that the theory has to be converted into quantitative relations between several processes and parameters. Examples could be the link between the wound healing rate and the cell division rate, which often changes with, for instance, the age and lifestyle of the patient. The quantification operation often leads to mathematical problems of varying complexity and nature depending on the purpose. In Figure 1, we show a scheme of gaining understanding in a quantification of wound healing research. We note that this scheme is generic in the sense that it holds for the quantification in all natural sciences and processes. Quantitative understanding of biological phenomena leads to predictive power as well as to a reduction of experiments, which can be expensive, time-consuming, dangerous, or are suffering from ethical constraints. Furthermore, quantitative insight is necessary for visualization and animations, which can be used for educational purposes to doctors (in particular useful for pharmacy), students, and patients. Computational models are a typical result from the quantification of biomedical processes. In this

Figure 1 A schematic of modeling approaches in the life sciences.

article, we will review some computational models and explain their strengths and weaknesses.

Evaluation of Several Mathematical Approaches

There exists a large variation in the nature of mathematical models for wound healing in the literature. The first models were conceptually very simple in the sense that some of them were able to predict the condition for the onset of wound healing (or tumor growth). An example was proposed by Adam (1999) for wound healing and in earlier works for tumor growth. Adam's model was based on the assumption that wound healing is initiated once the concentration of a generic growth factor exceeds a predefined threshold value. The growth factor is secreted in a so-called active layer, which reflects a narrow region around the wound edge (typically a ring) with an increased cellular activity in terms of cell division, cell migration (also referred to as cell motility), and cytokines production. Mathematically, the model is simple but elegant, and reads as

$$\begin{aligned} \frac{\partial c}{\partial t} - D\Delta c + \lambda c &= P\chi_{\Omega_a}(x), \quad t > 0, \quad x \in \Omega, \\ c(0, x) &= 0, \quad x \in \Omega. \end{aligned} \quad (1)$$

Here c represents the generic growth factor, Ω represents the tissue region. Further, Ω_a denotes the active layer around the wound, λ models a loss term due to diffusion of the growth factor away into the tissue or due to a chemical reaction, P models the regeneration of the growth factor in the active layer Ω_a , $\Delta c = \frac{\partial^2 c}{\partial x^2} + \frac{\partial^2 c}{\partial y^2}$, and χ denotes the indicator function, satisfying

$$\chi_{\Omega_a}(x) = \begin{cases} 1, & x \in \Omega_a, \\ 0, & x \notin \Omega_a. \end{cases} \quad (2)$$

It is then postulated that wound healing is initiated at each position of the wound edge, Γ , if and only if

$$c(t, x) \geq \theta, \quad x \in \Omega_a.$$

It is well known that the solution to the above partial different converges to a steady-state equilibrium as $t \rightarrow \infty$. Therefore Adam originally considered the steady-state solution only as a predictive model to forecast whether the wound with given dimensions would start healing at all. Javierre *et al.* (2009) extended the model with a free boundary problem where the wound edge is allowed to move according to phenomenological law depending on the local growth factor concentration and the local wound edge curvature, which reads as

$$v_n = H(c - \theta) (\alpha + \beta \kappa) \quad (3)$$

where v_n denotes the normal velocity on the wound edge directed into the wound, α and β are constants and $H(\cdot)$ is a Heaviside function. The free boundary problem was solved using a level-set method. Though the model is simple and elegant from a mathematical problem, it only contains a very limited amount of biological information as it is well known that wound healing is a very complicated biological process.

In order to incorporate more biology into the model, such as mechanical factors and the interplay between several cellular phenotypes and for instance the interplay with angiogenesis as well as with the immune response system, the model is way too simple. However, on the testing of cellular monolayer cultures consisting of one cell only, healing of a gap can be simulated and readily validated using this class of models. Then, one could mimic, for instance, the closure of the epidermis that consists of keratinocytes as a thin cellular layer. Note that this model only tracks an interface between the 'wounded state' and the 'undamaged state' and hence does not involve any cellular densities, or any explicit information on the number of cells.

A next class of models treats cellular densities in terms of an averaged number of cells per unit volume or per unit area. Here one could for instance consider the interplay between a generic growth factor and the migration, proliferation, and death of a cellular phenotype. This class of models already contains some more biological information than the previous class. An example of this class is the model that was originally formulated by Sherratt and Murray (1991), which reads as

$$\begin{aligned} \frac{\partial n}{\partial t} - D\Delta n + kn &= s(c)n \left(2 - \frac{n}{n_0}\right), \\ \frac{\partial c}{\partial t} - D_c\Delta c + \lambda c &= f(n), \\ f(n) &= \begin{cases} \lambda c_0 \frac{n}{n_0} \cdot \frac{n_0^2 + \alpha^2}{n^2 + \alpha^2}, & \text{for the activator,} \\ \frac{\lambda}{n_0} \frac{c_0}{n}, & \text{for the inhibitor,} \end{cases} \\ s(c) &= k \left(\beta + \frac{2c_m(h - \beta)c}{c_m^2 + c^2} \right). \end{aligned} \quad (4)$$

Here n and c , respectively, denote the cellular density and the growth factor concentration. Migration is assumed to proceed by random walk (linear diffusion). Here α , β , λ , k , c_m , c_0 , n_0 , and h represent model constants for cellular proliferation and death as well as for the regeneration of growth factors. Note that here α and β have a different meaning than in the previous model. This model falls into the class of 'transport-reaction models.' The model contains the regeneration of growth factors by the cells, which could be epithelial cells and the influence of this growth factor on the proliferation of the epithelial cells. Although this model already falls into the class of relatively simple models, it does contain more biological information as it is able to be used for the prediction of skin quality via the quantity n , which is no longer models a binary state between 'wounded' and 'undamaged' as in the previous model. Clear advantages of this class of models is that they are still analytically tractable in a framework of stability and traveling wave analysis, which was carried out by Sherratt and Murray (1991). We remark that this model serves as an example but that many more references could be given for this class of models, see for instance (Britton and Chaplain, 1993; Olsen *et al.*, 1995; Alarcon *et al.*, 2006; Gaffney *et al.*, 2002; Maggelakis, 2003).

Later extensions of this model were constructed to combine the formalism with angiogenesis, wound contraction by, among others, Javierre *et al.* (2009). These processes lead to the incorporation of more reaction-transport equation

including all kinds of nonlinear couplings as well as to the coupling with mechanical models. The coupling with mechanical models also leads to modeling local deformations and displacements in the tissue region, which also needs an appropriate treatment of mesh displacements. Nowadays, very complicated models exist where many of the biological subprocesses have been incorporated, which hence need a large number of input (model) parameters as well as elaborate 'numerical' schemes based on 'discretization' techniques such as 'finite-element methods' and 'numerical time-integration schemes.' Advantages are that much of the important biology is simulated and that the link between (partly) overlapping biological subprocesses can be studied. On the other hand, many of the biological parameters that serve as input parameters in the models are very hard to determine or even in some cases impossible to determine. Having such an uncertainty in the parameters, it is necessary to carry out sensitivity analyses over wide ranges of parameter values. For simple models involving a few unknown parameters, this is not a hard task and the display of healing characteristic over different parameter regimes allows a visualization in terms of tractable plots of 'level-curves' of the parameter ranges. For the more complicated models, the visualization and presentation becomes more challenging and probably stochastic methods such as 'stochastic' methods could be helpful. One of the drawbacks of this class of complicated models is the uncertainty of the parameter values that reduces the predictive power of these models. A big advantage of the continuum-based models is that they can be used easily over large scales such as the tissue or organ scale. The stochastic variations may not be implemented in single runs, but if averages of the parameter values would be known, then, the model outcomes could be interpreted as average experimental outcomes.

Until now all models fell within the 'continuous-scale' formalisms, which were formulated in terms of partial differential equations. Another class of models is discrete in the sense that a domain of computation, which is a tissue, is divided into a set of 'lattice volumes or areas' that have a binary (or discrete) state. The state could reflect 'wounded' or 'undamaged' in the binary case of wound healing. This class is referred to as 'cellular automata models.' Each lattice volume is allowed to change according to 'deterministic' or 'stochastic' principles and often its change of state is determined by the state of the neighboring lattice volumes or by the change of state of the neighboring lattice volumes. One can also determine the change of state by optimality principles that are possibly based on energetic foundations. This class of modeling, referred to as the 'cellular Potts models,' has had large popularity in various branches of statistical and theoretical physics. Graner and Glazier (1992) introduced this type of modeling to simulating 'angiogenesis,' which is the regeneration of a vascular network. Merks and Koolwijk (2009) has worked on getting this modeling to higher levels regarding angiogenesis, where extensions have been made to model deformation and migration of individual endothelial cells. Since this model makes use of a lattice, it is suitable to enrich the formalism with numerical discretization schemes for the solution of partial differential equations that mimic regeneration, decay, and transport of chemokines, oxygen, and other chemicals. Disadvantages are the need of a lattice where

simulations may exhibit lattice-dependent behavior and the need of large computational resources. A three-dimensional implementation of the model still seems to be cumbersome. Although the biological processes are simulated quite well and different biological hypotheses can be set as input parameters into the model. This modeling class also contains a stochastic nature, and hence several runs are needed to predict the average behavior as well as variances needed for the evaluation of intervals of confidence. Modeling large cell colonies also poses a computational challenge whereas this is solved relatively easily by the continuum-scale models.

Other modeling approaches are based on particle methods, where individual cells are treated as spheres or circles of finite radius to deal with cell proliferation, death, differentiation, migration, etc. Here contact forces between cells that physically collide are incorporated. One often uses energetic principles where mechanical factors, as well as chemical factors are incorporated. Recent approaches were described in Groh and Louis (2010), Neilson *et al.* (2011), Byrne and Drasdo (2009), Rey and Garcia-Aznar (2013), and Vermolen and Gefen (2012a). Some of the models were constructed with the help of the experimental observations by Reinhart-King *et al.* (2008) that remote cells communicate over distances of the order of tens of micrometers by mechanical forces they inflict on the substrate or collagen. The approaches contain stochastic processes like cell death and proliferation and cell migration, where for instance diffusion is modeled by a Wiener process for the spatial position of the cells, for example, by the following 'stochastic differential equation' (Steele, 2001)

$$dx(t) = \sigma dW(t) + v(t)dt, \quad (5)$$

where $x(t)$ represents the position of a cell, $W(t)$ denotes a vector Wiener process, and $v(t)$ stands for the 'deterministic' component of the cell velocity. This deterministic cell velocity can contain all sorts of contributions such as 'haptotaxis' or 'chemotaxis.' A characteristic of this modeling class that the cellular positions are not limited to a discrete set of points in space but may migrate over a continuous (compact) domain reflecting a part of tissue. The absence of a lattice on which cells are present, allows a treatment without 'computational meshes' such as the use of 'Fundamental Solutions (Green's Functions)' (Evans, 1998), 'superpositions' over finite sets of sources for the chemokines or displacements treated in the model. Also 'integral' expressions involving 'convolutions' over Fundamental Solutions are commonly used to obtain the concentrations due to secretion over a continuous area of sources. An example of such studies can be found in Vermolen and Gefen (2012b). In other cases, one uses a 'hybride' formalism where chemical concentration, mechanical displacements, etc., are resolved using 'discretization' techniques such as the 'finite-element method.' Since this class of models can be extended with 'stochastic' principles, several runs have to be made in order to be able to draw any 'statistically' sound conclusions. This kind of models is very suitable if one is interested in collective cell behavior where one typically considers cell colonies of approximately tens of thousands of cells. To consider more cells, one will have to rely on parallel computational environments such as graphical processing units (GPU) and/or CUDA. We show an example of the outcomes of such a model in Figure 2, where snapshots at consecutive

Figure 2 Some snapshots of a healing wound at times 0, 13.3, 15, and 100 h with constituent cells (red) pathogens (black dots) and immune cells (white).

times are shown during closure of a gap. The computations done with a cell-colony model mimic a monolayer cell-culture.

A subclass of this modeling work is represented by cellular models where apart from the migration, differentiation, and death of cells, one also incorporates the deformation of cells. The shape of the cell changes during migration or during differentiation to another phenotype. For this type of models, various approaches have been reported in literature. The information that one extracts from these models is very detailed concerning single-cell behavior or for the behavior of small colonies (numbers) of cells. In some cases one solves the visco-elastic equations on a moving and deforming domain using 'finite-element methods' with a moving surface. This is done by [Madzvamuse and George \(2013\)](#). This method allows the incorporation of much of the physics behind migration and cell deformation, but it also needs the solution of a three-dimensional problem with a moving boundary, which demands quite some computational power for a single cell. In other cases, one approximates the cell boundary by a 'computational' mesh and one links all neighboring points together and to the cell nucleus by applying 'spring forces,' by which a set of equations of motion for the cell nucleus and the discrete set of points on the cell boundary (cell membrane) is obtained. This system of equations is linked with the inclusion of

chemotaxis or any other type of deterministic way of motion (one can even apply this to cell migration in blood vessels, where the velocity is determined by an interaction with fluid flow). A Wiener process may be used to model the diffusional contribution to cellular migration. This approach was carried out by [Vermolen and Gefen \(2013\)](#) for chemotaxis (and extended by [Vermolen et al. \(2014\)](#)) for the case of cellular migration through small blood vessels to model the immune response system prior to wound healing. The latter approach allows a simple treatment for multiple cells but it still requires more computational resources than the previous class based on particle methods. Advantages are the enormous cellular details that one can derive from the models, and the ability to visualize elementary biological processes such as cell migration, division, differentiation, etc. The last-mentioned processes can be modeled using both deterministic, see [Prokharau et al. \(2014\)](#) for instance and (semi-)stochastic principles. Biologists are able to predict when a cell divides upon knowing the time-history and environmental situation of the cell. Since this information is not available for large colonies of cells, one has to rely on (semi-)stochastic principles to model these processes. The addition of stochastic principles can be done using Poisson processes or by incorporating Wiener (jump) processes or by adding randomness to the initial stages of the cells.

Conclusions

In this article several classes of models have been considered that can be used to mimic (partial) processes related to wound healing or even to tumor growth. We remark here that the treatment is far from complete in the sense that far more models exist in the literature on the mathematics of wound healing. However, the present article aims at being descriptive concerning all kinds of modeling approaches. The models are based on various scales, ranging from tissue-scale down to cellular scales. If one wants to look at large-scale issues related to wound healing, such as the influence of curvature on healing rate or on the velocity of the interface separating the wound from the undamaged tissue, then one is recommended to use the large, continuum-scale models. Furthermore, small-scale events as the migration of individual cells can be studied and visualized using cellular-scale models such as particle-inspired models or cellular automata models. The results of these simulations could be compared to *in vitro* and *in vivo* experiments and subsequently be used as input in the large-scale (tissue-scale) models.

Next to the spatial levels, mathematical models range in complexity. Complex models can be used to study links between subtle biological processes on several levels. However in many applications one is not interested in large detail but merely in the reproduction of trends. For these last-mentioned cases, one could rely on relatively simple models. Complicated models have the disadvantage of the need of many input parameters, which hardly ever have been measured, or which even are not measurable at all. In this sense, successful modeling of biological processes like wound healing relies on a rigorous model-reduction and this is where the most interesting modeling challenges originate from.

Another issue is the uncertainty in the measured parameters due to measuring errors or due to patient-specific values of parameters as a result of sex, pigmentation (race), lifestyle, age, and physical condition. One can develop very accurate numerical schemes to approximate the solution to the mathematical modeling problem, but the approximation is of limited use if the input parameters already contain large uncertainties.

Introduction

How does the genetic information encoded in the DNA direct the growth and form of multicellular organisms? This extremely challenging question has traditionally been addressed in developmental biology by analyzing the scales in isolation from one another. Classical embryology has looked at multicellular development from the perspective of individual cells and tissues. It showed, for example, how a specific portion of the early embryo called the ‘the organizer’ could elicit the formation of the body axis, or how the mesodermal tissue induces the ectoderm to turn into the neural plate. Molecular genetics has looked at the function of individual genes in the development. Here it was investigated how the knock-out or overexpression of individual genes affects the structure of the organism as a whole, whereas cell biology investigates the functionality of genes and proteins in individual cells. High-throughput molecular approaches, including genomics, transcriptomics, and proteomics, have made it possible to investigate the activity of all genes in the developing organism concurrently. However, a complete understanding of biological development requires us to integrate information from the molecular, cellular, and tissue level scales, monitoring events occurring at timescales ranging from nanoseconds (chemical reactions) to years (homeostasis of organisms) to millions of years (evolution). The complexity of multiscale interactions makes it almost impossible to capture biological development using experimentation alone. Recent multiscale systems biology studies that use a combination of imaging, experimentation, combined with multiscale modeling, and simulation can help provide new, surprising insights into the mechanisms of biological development.

Vertical Integration

In this article we will discuss how multiscale, computational modeling helps biologists to analyze the interactions between the molecular, cellular level, and tissue levels during biological development. These approaches make use of ‘vertical integration’: they merge mathematical and computational models formulated at different spatial and/or temporal scales to produce multiscale models.

Recent insight into the development of the horizontal stripe pattern of the zebrafish is a good illustration of vertical integration. Zebrafish with a mutation in a gene called *jaguar* have two diffuse, dorsal and ventral blue bands, instead of the usual, horizontal stripe pattern. How does a defect at the molecular level (a gene mutation) affect a phenomenon at

the level of the organism (the fish pattern)? Naively, one would perhaps expect that *jaguar* must encode a gene directly involved in skin pigmentation, for example, a pigment protein. Instead, *jaguar* codes for the ion channel Kir7.1. How can an ion channel impact the coat patterns of zebrafish? Kir7.1 is involved in the polarization of melanophores, the black pigment cells responsible for the stripes’ black color. Upon touching the xanthophores (yellow pigment cells), the melanophores depolarize and move away (Inaba *et al.*, 2012). At the multicellular level, this behavior separates melanophores and xanthophores, a process that is thought to be part of a Turing-type patterning mechanism (Nakamasu *et al.*, 2009), although this conclusion was challenged recently (Mahalwar *et al.*, 2014). Thus in the *jaguar* mutant, the loss of a crucial ion channel in melanophores changes their ‘cell behavior,’ the response to xanthophores. Eventually this changes the tissue-level patterning of zebrafish stripes.

This work on zebrafish patterns offers a relatively simple example of how genetic information regulates the organism’s phenotype, by changing the behavior of the individual cells. In the analysis of this chain of events, detailed molecular information is replaced by a course-grained description of how the genetic change affects the behavior of individual cells and their responses to one another. Mathematical descriptions at the cell population level then demonstrate how a defect in cell behavior eventually changes the cells’ collective behavior leading to a change in skin patterning. This article will describe how to apply vertical integration to the analysis of multicellular systems, using a combination of imaging and computational modeling. We will illustrate the approach based on practical examples in animal and plant developmental biology.

Analyzing Cell Behavior

Recent technical developments have made it possible to analyze the behavior of individual cells and cell populations to unprecedented quantitative detail. Systems microscopy approaches can characterize the motility and shapes of cancer cells in cell cultures under a large number of conditions (Le Dévédec *et al.*, 2010). Detailed quantitative analyses of cell migration are also performed of B-cells in germinal centers (Beltman *et al.*, 2011), of endothelial cells *in vitro* (Parsa *et al.*, 2011) and of cells in the tail bud during somitogenesis (Dray *et al.*, 2013). It has now also become possible to concurrently image the trajectories and lineage of cells in organs (Short *et al.*, 2014) and early zebrafish embryos (Olivier *et al.*, 2010). The latter line of work is now resulting in a digital gene expression atlas of early zebrafish embryogenesis

(Castro-González *et al.*, 2014). This type of work is now increasingly complementing high-throughput molecular data. It provides exactly the type of data needed to inform multicellular simulation models and to validate the model predictions. In order to annotate and efficiently store such multicellular, cell-behavioral data in a format that can directly act as direct input for multicellular simulations, several groups are developing new data standards including the Cell-behavioral Ontology (Sluka *et al.*, 2014) and MultiCellDS (see Section Relevant websites).

Alongside high-throughput imaging approaches to analyze collective cell behavior, it is also necessary to map out the reactions of individual cells in response to the stimuli the cells receive from adjacent cells and chemical signals. These stimulus-response maps then are the input for the cell-based, multicellular simulation models that the remainder of this article will describe. An example of such a description of cell behavior is the behavior of melanophores in response to contact with xanthophores described in the previous section. The descriptions can be derived from *in vivo* observations (Mahalwar *et al.*, 2014) or by isolating the cell types *in vitro* (Inaba *et al.*, 2012). Using microfluidic approaches it is also possible to quantify the chemotactic response of cells to signaling gradients (Lin and Butcher, 2006) or the pairwise interactions between cells (Yin *et al.*, 2008; reviewed in Merks and Koolwijk, 2009). A number of measures have been designed to quantify the accuracy of chemotaxis (Kay *et al.*, 2008).

Mathematical Models for Studying Collective Cell Behavior

Depending on the biological application, a range of cell-based modeling approaches are commonly used. Cell and tissue-level models are roughly categorized into continuum and single-cell-based models, for which we give a short overview. In tissue morphogenesis, also the surrounding extracellular matrix (ECM) plays a key role in regulating and coordinating cell behavior. To describe interactions between cells and the ECM a range of modeling studies have combined single-cell-based models with continuum or discrete representations of the extracellular matrix. A brief overview of such hybrid approaches will be provided here as well.

Continuum Models

A population of cells can be considered as a continuum (Murray *et al.*, 1983), and thus be modeled as a density function. In this case, the movement of cells is described by a continuity equation. In a general form, this is

$$\frac{\partial n}{\partial t} + \nabla \cdot \vec{J} = \sigma \quad [1]$$

where n is the cell density, $\vec{J}$ is the flux of cells and σ describes the emergence or removal of cells in the tissue. Typically, diffusion ($\vec{J} = D\nabla n$) and migration of cells ($\vec{J} = \vec{v}n$) is incorporated. The partial differential equation (PDE) can be extended to account for cell behavior. Cellular birth and death events, such as apoptosis and mitosis, are generally included in

the σ term. Phenomena that influence cell migration can be described in terms of the flux $\vec{J}$. For instance, Namy *et al.* (2004) included haptotaxis, Byrne and Drasdo (2009) simulated movement down pressure gradients and Manoussaki *et al.* (1996) implemented mechanotaxis.

Discrete Models

Continuum descriptions of cell populations can become limiting when the models must be validated against individual cell trajectories, or in case the structures of interest form at a length scale of only a couple to tens of cells. Discrete, cell-based models describe cells as individual elements, and can be very useful in such situations. Single-particle models represent cells as point particles or ellipsoids. Multiple-particle-based models use a collection of particles to represent each cell, allowing for a more detailed description of cell shape (Merks, 2013). A further distinction is made between representations on regular lattices, which can be computationally more efficient, and off-lattice representations. We present an overview of cell-based methodology in Figure 1.

Particle-based models

In single-particle-based off-lattice models, cells are typically represented as point or ellipsoid particles. When using a lattice, cells are represented as one lattice site. Not only does the way cells are represented vary among models, but the way movement is simulated differs as well. Differential equations of motion for each particle can describe cell migration. These typically consist of a cell motility term to describe active, random, or directed cell motion, and an external force consisting of a sum over the forces exerted by all the other cells and the environment (see, e.g., Grégoire *et al.*, 2003). Alternatively, particles comply to a set of behavioral or migratory rules (see, e.g., Byrne and Drasdo, 2009). Using particle-based methods, various cell migration behaviors have been modeled. For instance, Szabo *et al.* (2007) included diffusion, directional persistence, and an attraction to anisotropic structures to model cell organization into network-like patterns. Cell-cell interactions, such as pressure and velocity adaption to neighbors, were added by Sepúlveda *et al.* (2013) and Byrne and Drasdo (2009) respectively. In Dallon (2000) haptokinesis and chemotaxis were simulated; and a particle-based model of contact guidance was presented in Dallon *et al.* (1999).

While these particle-based methods make it possible to investigate how interactions between spherical or ellipsoid cells can give rise to cell motility during embryogenesis, they cannot account for cell shape changes, which are key to many developmental processes. To account for differential cell shape, multiple particle methods describe cells as a collection of connected particles, defining either the boundary or interior of the cells. Thus, in these methods cell shape is explicit and can change actively during simulations or passively in response to interactions with adjacent cells. The subcellular elements method (Newman, 2005) is an example of an off-lattice multiple particle method, where cells are divided into subcellular elements (for instance, points in space), which can locally interact with elements of the same cell and elements of other cells via equations of motion. These equations describe

Figure 1 An overview of cell representations in cell-based simulation methodology. Modified from Merks, R.M.H., 2013. Cell-based modeling. In: Enquist, B. (ed.), Encyclopedia of Applied and Computational Mathematics. Springer. Available at: <https://www.springerreference.com> (accessed 02.06.15).

both the internal rheology of individual cells, as well as the adhesive and repulsive forces with adjacent cells. Mechanotactic and chemotactic cell migration can also be included (see, e.g., Sandersius and Chuai, 2011). Alternative off-lattice and lattice-based multiparticle methods are the vertex-based models and the Cellular Potts model (CPM), which will be described in more detail in the next sections.

Vertex-based models

Vertex-based models describe tissues as a network of polygonal cells, which are characterized by the position of vertices v_i , with $i=1, \dots, N_V$, where N_V represents the total number of vertices, together with a set of N_E edges e_{ij} which connect vertices i and j . Each polygon corresponds to a cell indexed by $\alpha=1, \dots, N$, where N is the total number of cells in the system. Vertices are displaced depending on a Hamiltonian (H) energy function that describes the force balance of the system, or using explicit equations of motion.

Jülicher and coworkers use the Hamiltonian (Farhadifar et al., 2007),

$$E = \sum_{\alpha} \frac{K_{\alpha}}{2} \left(A_{\alpha} - A_{\alpha}^{(0)} \right)^2 + \sum_j \Lambda_{ij} l_{ij} + \sum_{\alpha} \frac{\Gamma_{\alpha}}{2} L_{\alpha}^2 \quad [2]$$

Here, the first term is a cellular volume conservation term, where K_{α} is an elastic coefficient, A_{α} is the area of cell α and $A_{\alpha}^{(0)}$ is the resting area of the cell. The second term represents cell membrane tensions, Λ_{ij} , at the junctions between cells, with l_{ij} denoting the length of edge e_{ij} . The third term describes the contractility of cell perimeter L_{α} by a factor Γ_{α} . Additional rules allow adjacent cells to detach from one another, a so-called T1-transition. The local minima of the energy function determine the tissue configurations, which the authors used to identify cell packing geometries of the epithelium of the fruit fly *Drosophila* (Farhadifar et al., 2007).

Merks et al. (2011) presented a closely related vertex-based approach to analyze plant morphogenesis. This method typically used additional nodes to allow the cell-cell interfaces to

bend, while T1-transitions are suppressed to more closely mimic plant tissues in which cells cannot move relative to one another, and allows cell walls to move according to turgor-driven cell expansion laws: when there is an intracellular turgor pressure applied uniformly on the cell walls, the elastic properties of the walls will counteract it. These mechanics are described by the following Hamiltonian,

$$H = \lambda_A \sum_{\alpha} \left(A_{\alpha} - A_{\alpha}^{(0)} \right)^2 + \lambda_M \sum_j \left(l(j) - L_T(j) \right)^2 \quad [3]$$

where A_{α} and $A_{\alpha}^{(0)}$ have the same meaning as in the Jülicher model, $l(j)$ represents the length of wall j , $L_T(j)$ is the target length for wall j in the absence of turgor pressure, λ_A is a parameter for the cells' resistance to compression or expansion, and λ_M is a spring constant. The Metropolis algorithm is used to minimize H . Here, a node of the network is selected randomly and then moved in a random direction by a set distance. The algorithm always accepts the movement when the energy difference ΔH given by this movement reduces the energy of the system. Otherwise, the movement is accepted with a Boltzmann probability:

$$P(\Delta H) = \begin{cases} 1 & \text{if } \Delta H < 0 \\ e^{-\Delta H/T} & \text{if } \Delta H \geq 0 \end{cases} \quad [4]$$

where T describes the amount of randomness in the system. Using this model, one can also incorporate intracellular reactions and transport of chemicals by formulating them in a PDE and solving it after each Metropolis cycle. This model is implemented in the open source package VirtualLeaf (see section Relevant Websites).

The vertex-based models presented above only have two-dimensional (2D) implementations, but recent breakthroughs consider three-dimensional (3D) tessellations. A base model for the 3D approaches is the one developed by Honda et al. (2004) who express a cell as a polyhedron. Network dynamics

is modeled by prescribing an equation of motion to each vertex i

$$\eta \frac{d\mathbf{r}_i}{dt} = - \frac{\partial U}{\partial \mathbf{r}_i} \quad [5]$$

where $\mathbf{r}_i$ is a 3D position vector of vertex i , η is a viscosity coefficient and U is a potential force, which can be related to cell surface area, cell volume, or external forces. Computer simulations of this model showed that in the absence of external forces, cell aggregates become spherical to minimize individual cell surface areas, whereas under a continuous external force, the cells slowly rearrange themselves to recover their original shape while the aggregate remains flat. This model was recently extended in [Okuda et al. \(2013a\)](#) to include cell division, of which the direction was shown to influence tissue morphology ([Okuda et al., 2013b](#)). Related vertex-based, 3D models have been presented for simulations of cell sorting ([Hutson et al., 2008](#)) and for plant-tissue modeling ([Boudon et al., 2015](#)).

CPM

The CPM ([Glazier and Graner, 1993](#)) represents cells as a set of connected lattice sites. Each lattice site, $\vec{x}$, has a state $\sigma(\vec{x}) \in \{0, 1, \dots, n\}$ that identifies the individual cell the lattice site belongs to. $\sigma=0$ represents the surrounding medium, and n is the total number of cells in the lattice. Forces acting on the cells are described in the Hamiltonian,

$$H = \sum_{(\vec{x}, \vec{x}')} J(\sigma(\vec{x}), \sigma(\vec{x}')) (1 - \delta(\sigma(\vec{x}), \sigma(\vec{x}'))) + \lambda \sum_{\sigma \in [1, n]} (a_\sigma - A_\sigma)^2 \quad [6]$$

where J is an adhesive energy between cells and δ is the Kronecker delta function ($\delta(x, y) = 1$ if $x = y$ and $\delta(x, y) = 0$ otherwise) such that the first term counts the total adhesive energy across cell-cell and cell-medium interfaces. The second term is a cellular volume conservation term, with a_σ the cell area, A_σ the resting area of cell σ , and λ a compressibility parameter.

To mimic cell motility and membrane fluctuations, the CPM iteratively attempts to copy the state $\sigma(\vec{x})$ of a randomly selected lattice site $\vec{x}$, into a randomly selected, adjacent lattice site $\vec{x}'$; if such a copy reduces the value of the Hamiltonian ($\Delta H \leq 0$), it is accepted. If the attempt would increase the value of the Hamiltonian ($\Delta H > 0$) it is accepted with a Boltzmann probability, $P(\Delta H) = \exp(-\Delta H/T)$. These copy steps account for the intrinsic random motility of cells, with large values of T corresponding with more random motility. During one time step, N such copy attempts are made, with N the total number of lattice sites in the lattice.

The CPM has been extended with many algorithms accounting for additional cell behaviors, which are typically described by additional terms in the Hamiltonian (eqn. [6]). Of particular interest are the hybrid CPMs, in which the CPM is combined with discrete continuum models (PDEs) to account for secreted chemical signals ([Savill and Hogeweg, 1997](#)) or an elastic substrate ([van Oers et al., 2014](#)). Other extensions include anisotropic cell adhesion ([Zajac et al., 2003](#)), cell elongation ([Merks et al., 2006](#)), and persistent cell motility ([Turner and Sherratt, 2002](#)). The open source software

package 'CompuCell3D' ([Swat et al., 2012](#)) provides a user-friendly interface to the CPM and acts as a community-driven portal for the exchange of published models and extensions.

Modeling Cell-ECM Interactions

The cell-based models described above focus primarily on describing collective cell behavior. Cells in actual tissues are surrounded by the ECM, consisting of extracellular molecules and fibers, to which cells adhere. Besides functioning as a support for cells, the ECM also guides cell migration. Cells, for instance, move up ECM density gradients (haptotaxis) and chemoattractant gradients (chemotaxis). Moreover, cells have been shown to migrate toward stiffer areas (durotaxis) and along fibers (contact guidance). Not only do cells respond to the structure of the ECM, but they also actively change and remodel its local architecture. Cells are for instance able to secrete ECM-degrading enzymes. By applying a force on the ECM, cells can locally stiffen the ECM and reorient fibers. Thus, tissue morphogenesis is highly dependent on the active interactions between cells and the ECM. It is important, therefore, to couple cell models with models describing the ECM. Similar to cells, depending on the context and objective, the ECM can be modeled as a continuum or by using discrete elements. Cell-ECM interactions can be simulated by coupling the PDEs that describe cells and the ECM. For instance, both [Manoussaki et al. \(1996\)](#) and [Namy et al. \(2004\)](#) used this to study mechanical cell-ECM interactions during angiogenesis. In the CPM, ECM materials can be represented by generalized cells, using additional values of σ ([Dias et al., 2014](#); [Tahir et al., 2015](#)). To model the ECM in more detail, for example, taking into account the density, structure, or mechanics of the ECM, hybrids between cell-based models, and continuum models for the ECM are often used. Examples include the work by [Das et al. \(2010\)](#), [Bauer et al. \(2009\)](#), and [Daub and Merks \(2013\)](#), who coupled a cell-based model with PDE models of the extracellular environment, to study how chemical remodeling by the endothelial cells can facilitate sprout splitting. Interactions between cells and fibers in the context of wound healing was studied using a coupled cell-based model with a continuous model for the fibers by [Dallon \(2000\)](#) and [Cumming et al. \(2010\)](#). To model the mechanics of the ECM, [Bischofs and Schwarz \(2003\)](#) studied the orientation of cells on a deformable substrate. [Checa et al. \(2014\)](#) and [van Oers et al. \(2014\)](#) introduced hybrid finite-element and cell-based models to simulate mechanical communication of cells on deformable substrates. In these models the cells deform the substrate, and the cells respond to local deformations of the substrate. The resulting feedback loop suffices for co-alignment of cells and pattern formation, for example, networks and angiogenic sprouts. As the ECM has a fibrous nature, it can also be modeled in a discrete fashion and be combined with a cell-based model, which was done by [Schlüter et al. \(2012\)](#) and [Reinhardt and Gooch \(2014\)](#) to study the migration of cells on a compliant substrate.

Examples of Vertical Integration Studies

Collective cell behavior is a key factor in many developmental processes. In this section we describe how cell-based modeling

has been used in combination with knowledge from experiments to elucidate which cell behaviors are required to form a specific cell pattern or tissue.

Differential-Adhesion Driven Cell Sorting

Townes and Holtfreter (1955) observed that if embryonic cell types are dissociated, mixed, and reaggregated *in vitro*, they segregate into two homogeneous clusters with one cell type covering the other with relative, anatomically correct positions. To explain this phenomenon, Steinberg (1963) proposed the differential adhesion hypothesis, which states that differences between intercellular adhesiveness may drive cell sorting, such that cells with weak intercellular adhesiveness separate from one another and cells with stronger adhesion tend to stay together. Graner and Glazier (1992) and Glazier and Graner (1993) introduced the CPM to explore this hypothesis computationally (see Section CPM). Depending on the relative intercellular adhesions strengths, the CPM predicts that differential adhesion can give rise to different sorting patterns. Two mixed cell types segregate into clusters if they adhere more strongly to their own type (homotypic adhesion) than to the other type (heterotypic adhesion). Checkerboard patterns form if the heterotypic adhesion is stronger than the homotypic adhesion. The observation of Townes and Holtfreter (1955) is reproduced if cells with relatively weak homotypic adhesion (but stronger than the heterotypic

adhesion) are mixed with a second cell type of stronger homotypic adhesion (Graner and Glazier, 1992; Glazier and Graner, 1993). The cell type with strong homotypic adhesion then moves to the center of the cluster, where it can establish most connections with its own cell type.

The classic Townes and Holtfreter (1955) experiments were reexamined using quantitative methods by Krieg *et al.* (2008) who observed the segregation of zebrafish endoderm progenitor cells, mesoderm progenitor cells, and ectodermic progenitor cells (Figures 2(a) and 2(b)). Atomic force microscopy yielded measures of the relative strengths of homotypic and heterotypic adhesion of each of the three cell types. All heterotypic adhesion strengths were roughly equal and equivalent to the homotypic adhesion of the ectoderm; the endoderm adhered to itself more strongly than to the ectoderm, and the mesoderm adhered most strongly to itself among the three progenitor cell types. Interestingly, with these relative adhesion strengths, the cells sorted the wrong way out in the CPM, with the mesodermal cells moving to the center of the aggregate instead of the periphery as in the experiment. The authors therefore examined a second source of interfacial tension in the CPM, actin-mediated cortical tension. Ectoderm progenitors had the highest actomyosin-dependent cell cortex tension, followed by mesoderm and then endoderm progenitors. After including this source of interfacial tension the CPM simulations matched the experiments (Figure 2(c)) suggesting that a combination of differential cell adhesion and

Figure 2 Experimental and computational models of cell sorting. (a) Schematic drawing of an *in vitro* cell sorting assay, during which two types of progenitor cells are mixed in a hanging drop and subsequently sort out (Krieg *et al.*, 2008). (b) Time-lapse of the sorting of ectodermic and mesodermic progenitor cells *in vitro* (Krieg *et al.*, 2008). (c) Time-lapse of the sorting of ectodermic and mesodermic progenitor cells *in silico*, using a CPM-based model (Krieg *et al.*, 2008) in which cell sorting is driven by a combination of differential cell adhesion and differential cortex tension. (d) Time-lapse of the sorting of two cell types in an interfacial tension driven model based on the finite-element method. The outlines of the cells of the cell type that is in majority are visualized in light gray (Hutson *et al.*, 2008).

differential cortex tension is required to drive cell sorting. Indeed, disruption of the actomyosin-dependent cell cortex tension prohibited cell sorting. Random membrane fluctuations are required in the CPM for sorting, although a tension driven model based on the finite-element method introduced by Hutson *et al.* (2008) (Figure 2(d)) showed that these fluctuations are not required for topological untangling of cell types during sorting.

Vasculogenesis and Angiogenesis

Vascular networks are formed *de novo* from initially dispersed cells during embryogenesis, a process called vasculogenesis. Postnatally, blood vessels can branch or split (angiogenesis) to reach oxygen-deprived tissues, such as wounds and growing tumors. During angiogenesis and vasculogenesis, endothelial cells coordinate their behavior via chemical or mechanical signals and thereby collectively form multicellular blood vessel structures. Here we discuss computational models of angiogenesis, with a focus on cell-based models that study the

collective behavior of endothelial cells driving the formation of vascular networks (Figure 3(a)) and vascular sprouts.

Serini *et al.* (2003) proposed a continuum model for vascular network formation. In their model, endothelial cells attract one another by means of a secreted chemical signal, for example, vascular endothelial growth factor (VEGF). Based on this mechanism Merks *et al.* (2008) developed a CPM-based model. Surprisingly, although on short timescales the behavior of the model roughly resembled the continuum models, on a longer time scale the network-like pattern collapsed and the cells aggregated into spheroids. Merks *et al.* (2006) found that this chemotaxis-based model forms network-like patterns if cells assume an elongated shape. Palm and Merks (2013) later showed that chemotaxis is not necessarily required: a short-range adhesive force suffice for aligning elongated cells into branches. These connect to each other, thereby forming a network-like pattern. Szabó *et al.* (2008, 2007) and Szabó and Czirók (2010) showed that networks formed when cells preferentially adhere to elongated cells.

An alternative mechanism for network formation occurs if chemotaxis is inhibited at cell–cell interfaces (Figure 3(b)),

Figure 3 Experimental and computational models of blood vessel development. (a) Vascular network structure formed *in vitro* by human umbilical vein, endothelial cells (HUVEC). (b) Vascular network formation in the contact-inhibited, autocrine chemotaxis model (Merks *et al.*, 2008). (c) Vascular network structure formed by creation of a chemotactic VEGF gradient around the cells by secretion of VEGF-binding molecules (Köhn-Luque *et al.*, 2011). (d) Cells create mechanical strains in the extracellular matrix and form vascular networks by responding to the strains (van Oers *et al.*, 2014). (e) Angiogenic sprouting in a multiscale model, in which a fixed tip cell leads a sprout (Qutub *et al.*, 2009). The red node represents the migrating tip cell and black segments and nodes the quiescent vessel. (f) Cells compete for the tip cell position during angiogenic sprouting (Bentley *et al.*, 2014).

based on the experimental finding that bound VE-cadherin (an endothelial cell–cell adhesion molecule) modifies the response to VEGF-signaling (Dejana, 2004). These models, however, require rather short-range morphogen gradients, which are unlikely to occur based on measured diffusion coefficients of VEGF. Köhn-Luque *et al.* (2011) hypothesized, therefore, that cells do not secrete VEGF themselves, but produce extracellular components to bind externally present VEGF. In line with this hypothesis, fluorescently labeled VEGF accumulated in pericellular areas and colocalized with VEGF-binding molecules in an *in vitro* angiogenesis assay (Köhn-Luque *et al.*, 2013). Computational modeling showed network formation when cells chemotact toward ECM-bound VEGF (Köhn-Luque *et al.*, 2011; Figure 3(c)).

Besides chemical signals, cells can also respond to mechanical signals transferred through the surrounding ECM. Experimentally it was shown that cells respond to the strain in the matrix by orienting in the direction of stretch (Haston *et al.*, 1983) and that cells can also generate strain in the matrix themselves (Harris *et al.*, 1980; Winer *et al.*, 2009). Manoussaki *et al.* (1996) proposed a continuum, mechanical model of vascular network formation in which endothelial cells pull the ECM toward them along with the cells attached to it. Van Oers *et al.* (2014) proposed an alternative mechanical model based on a hybrid Cellular Potts and finite-element model. Here the CPM represents the cells and the finite-element model represents strains in the ECM. In accordance with experimental observations, in this model the strains in the matrix that one cell generates locally directs the motility of adjacent cells (see also Section Modeling Cell–ECM Interactions) adjacent cells. This mechanism suffices for network formation (Figure 3(d)) and sprouting.

During angiogenesis, endothelial cells differentiate into tip cells and stalk cells through lateral inhibition mediated by Delta-Notch signaling (Gerhardt, 2008). Tip cells are equipped with long filopodia to sense the local environment and guide the stalk cells along the sprout. A number of models have assumed that the tip cell is fixed and that it sets the path of the growing sprout (Milde *et al.*, 2008; Bauer *et al.*, 2007; Qutub *et al.*, 2009). For example, Qutub *et al.* (2009) developed a multiscale model in which cells are represented by nodes and segments. The node at the tip of the sprout represents the tip cell, which senses the environment to guide the growth direction of the sprout (Figure 3(e)).

More recently it was shown that cells continuously compete for the sprout tip position (Jakobsson *et al.*, 2010; Arima *et al.*, 2011), in line with the view that sprouting is a result of collective cell behavior. Bentley *et al.* (2014) used cell-based modeling to study the mechanisms of this tip cell competition. They modeled a preformed sprout covered by cells. Cells adhere to one another, crawl past each other and extend filopodia to sense external VEGF signals (Figure 3(f)). A model of Delta-Notch signaling included in each of the endothelial cells repetitively switched fate between tip and stalk cells. They showed that tip cell competition as experimentally observed by Jakobsson *et al.* (2010) was best mimicked if tip cells have less cell–cell adhesion than stalk cells and if tip cells extend more polarized myosin protrusions in the direction of the sprout tip than stalk cells.

Multiscale Modeling of Somitogenesis

A beautiful example problem that has been analyzed using vertical integration is somitogenesis, an early process that is key to vertebrate development (Figure 4(a)). Somites are composed of tightly bound aggregates of cells that are periodically separated from a continuous presomitic mesoderm (PSM) on each side of the neural tube (Hubaud and Pourqui, 2014). Later in development, the somites give rise to the vertebra, the skeletal muscles, and other associated structures (Baker *et al.*, 2008; Agero *et al.*, 2010). It is still not clear how a homogeneous PSM can convert into the regularly arranged periodic pattern of somites (Kondo, 2014) and it remains puzzling how differences in the number and size of the somites among different species occur. An attempt to understand this is by looking into how gene expression alters the behavior of cells and determine outcoming tissue architectures (Krieg, 2009; Schier and Talbot, 2005; Tepass *et al.*, 2002).

A periodic array of somites was originally proposed by Cooke and Zeeman (1976) to form by a clock and wavefront model that describes the presence of an oscillating gene expression (the clock) and its interaction with a posteriorly moving wave of extracellular signal (the wavefront). Although several theoretical models have been proposed to explain somitogenesis including the cell cycle model (Collier *et al.*, 2000; Stern *et al.*, 1988), the reaction diffusion model (Meinhardt, 1986), and the clock and induction model (Schnell and Maini, 2000), the clock and wavefront model so far has been the most widely accepted theory (Kondo, 2014; Grima and Schnell, 2007). A range of mathematical models following the clock and wavefront model cover one or more aspects of somitogenesis. Baker *et al.* (2006, 2008) have reviewed and implemented multiple one-dimensional (1D PDE) models for the segmentation clock, fibroblast growth factor 8 (FGF8) gradient, and cell adhesion. Recently, mathematical models have been developed and applied to elucidate the importance of Notch and Wnt signaling pathways and their crosstalk as an essential molecular mechanism during somitogenesis (Wang *et al.*, 2013). Hester *et al.* (2011) developed a CPM-based 2D multiscale integrated clock and wavefront model, including intercellular segmentation clock via Delta/Notch signaling, FGF determination front and differential cell–cell adhesion driven cell sorting. In this work, existing submodels of somitogenesis were combined to test if they could reproduce key dynamical and morphological features of somitogenesis (Figure 4(b)).

Recently, the role of a clock in the somitogenesis has been challenged. Non-somite mesoderm dorsalized with Noggin treatment can form ectopic periodic somite-like structures (Dias *et al.*, 2014). In a computational model based on the CPM, exposure to Noggin was assumed to initiate differentiation of polarized epithelial cells, which can gradually reorient into spherical structure in a differential-adhesion-driven cell sorting-like mechanism. This study suggests that somites are self-organizing structures that can form without a clock (Figure 4(c); Dias *et al.*, 2014). If and how the self-organizing properties of somites are guided or fine-tuned by the genetic oscillator in the PSM is a topic of ongoing research.

Regulation of Root Growth by Auxin in *Arabidopsis thaliana*

Auxin (indole-3-acetic acid or IAA) is a phytohormone that has been shown to control cell identity and cell expansion, and is major player in the regulation of root growth. Auxin diffuses freely inside the cells and cell walls and is thought to be actively transported between cells by membrane-bound specialized proteins from the PIN family. Figure 5(a) shows the positioning of the PIN efflux proteins alongside other efflux carriers like the ABCB proteins as well as influx AUX1/LAX

proteins. The polar localization of PIN-proteins leads to local differences in auxin concentrations in plant tissues, which control the cell growth and the frequency and orientation of cell divisions.

Cell-based models have been particularly instrumental in analyzing the role of auxin in root growth. Model simulations by Grieneisen *et al.* (2007) have shown how the patterned orientation of PINs in the root tip produce a flux pattern in the form of a reverse fountain and an accumulation of auxin at the quiescent center, a structure right above the root cap.

To understand the relation between this auxin dynamics and zonation in growing roots, the authors include the observation that higher auxin levels promote cell divisions, while lower levels were linked to cell elongation. Their simulations showed dynamical transitions between the elongation and meristematic zones qualitatively similar to what is observed *in vivo*, but with a highly stable auxin distribution around the quiescent center of the root. Thus, the PIN distribution may account for the formation of an auxin maximum as well as for changes in the zonation of the root.

Taking this idea a step further, Band *et al.* (2014) showed that the PIN efflux carriers alone cannot create the pattern of

auxin distribution at the root tip. Using a 2D vertex-based model with cell shapes segmented from DII-VENUS confocal microscopy images, they showed that influx carriers (such as the AUX1/LAX membrane proteins) are also required in controlling this distribution. Panel (c) of Figure 5 shows side by side the predicted auxin levels first in the case where the AUX1/LAX proteins are being knocked out and only PIN carriers ensure auxin dynamics, while the right figure shows the auxin levels when both PIN and AUX1/LAX control the active transport. Knowledge of the relationship between actual auxin levels and DII-VENUS sensor let the authors confirm their hypothesis that AUX1/LAX is essential in replicating realistic

Figure 5 Vertical integration applied to root development. Panel (a) represents a schematic extracted from Friml and Jones (2010) showing the molecular distribution of auxin transporters within a cell. Of particular interest are the PIN family efflux proteins and the AUX1/LAX influx proteins. Panel (b) presents the simulation results obtained by Grieneisen *et al.* (2007) while hypothesizing that PIN transporters are enough to create an auxin maximum in the root. The left figure represents the steady-state concentrations and one can see the arising maximum above the root cap. The right figure shows the auxin fluxes measured in $\mu\text{m}^{-1}\text{s}^{-1}$ which form the flux-reflux pattern. Panel (c) showcases the difference in auxin levels which arise after knocking out AUX1/LAX influx transporters (Band *et al.*, 2014). The left figure considers the auxin levels given solely by efflux PIN influence, while the right figure presents the resulting levels after including influx effects. Panel (d) displays the gravitropic response of statoliths visualized within columella cells of root tips at angles of 0°, 40°, and 90° to the horizontal as extracted from Band *et al.* (2012). The schematics show the 'tipping point' model where the statoliths redistribute auxin levels at the root tip (denoted by arrows).

auxin dynamics. Their study concludes that influx carriers control which tissues of the root will present high auxin levels, whereas the efflux PIN carriers control only the direction of auxin transport within these tissues.

Aside from internal factors, root development is also highly influenced by its surrounding environment, especially by gravity. A model which accounts for root gravitropism has been developed by Band *et al.* (2012) who made use of a downward pointing gravity stimulus. Their simulations showed that auxin gets redistributed from the upper side of the root to the lower side much faster than it takes the actual root to show bending effects. This supports the hypothesis that auxin redistribution regulates the root organ curvature. This auxin gradient only lasts for the first approximately 2 hours of the process (in the case of *A. thaliana*), after which auxin levels become again equal. The explanation for this may lie in the fact that the rapid loss of auxin level asymmetry occurred at a bending angle of approximately 40°, which could denote the tipping point for specialized statoliths which perceive gravity within columella cells as presented in panel (d) of Figure 5. The switch then in auxin flow at the root tip is likely to reflect the repositioning of the statoliths.

Conclusion

The above examples illustrate how detailed, cell-level imaging combined with multiscale, cell-based modeling can help unravel the mechanisms of biological development by which single cells form functioning, multicellular structures. An important asset of these models is abstraction and simplification of organizational levels (Merks and Glazier, 2005). Models of higher levels of organization (cells, tissues), typically coarse-grain the underlying molecular levels to a large extent. For example, to understand differential-adhesion driven cell sorting, it is not always necessary to unravel the molecular details of cell–cell adhesion; what matters most to the cell and tissue scale are coarse-grained physical measures: cell-type-dependent differences in cell adhesion strength and cortical tension. Similarly, to analyze how auxin regulates root growth and gravitropism, it is helpful to keep the big picture in mind and focus on the overall polarization patterns and the response to auxin. Of course, this is not to say that the molecular scale is irrelevant: the genes and molecules determine the logical ‘rules’ according to which cells behave and differentiate after receiving regulatory signals from the other cells, as well as their biophysical properties and integrated computational and experimental studies then help us reconstruct the collective cell behavior that we know as biological development.

Neurogenesis in the Adult Brain

MR Akins and ADR Garcia, Drexel University, Philadelphia, PA, USA

© 2016 Elsevier Inc. All rights reserved.

Introduction

For over a century, the idea that the mature central nervous system (CNS) was a fixed structure incapable of producing new neurons was a central dogma within the field of neuroscience. Neurogenesis, the production of neurons, was thought to be confined to early development. Though initially met with great resistance and controversy, compelling evidence beginning in the early 1980s and continuing through the early 2000s from birds, rodents, and eventually humans demonstrated that indeed the adult CNS undergoes continued neurogenesis in several brain regions throughout life (Goldman and Nottebohm, 1983; Eriksson *et al.*, 1998; Gage *et al.*, 1998; Doetsch *et al.*, 1999; Seri *et al.*, 2001). The discovery of adult neural stem cell (NSC) populations that produce new neurons in mature animals not only overturned a century-old fundamental principle of neuroscience, but also created a paradigm shift that has enhanced our understanding of the ways in which the CNS develops and is maintained throughout life. Indeed, a number of cellular processes that define and regulate adult neurogenesis have subsequently been identified in the developing CNS, illustrating shared fundamental properties between developmental and adult neurogenesis.

In the adult mammalian forebrain, NSCs are localized in two primary locations: the subgranular zone (SGZ) of the hippocampal dentate gyrus and the ventricular-subventricular zone (V-SVZ), an epithelium lining the lateral ventricles (Figure 1). SGZ stem cells produce granule cells that incorporate into the dentate gyrus of the hippocampal formation,

a structure critical for learning and memory processes (Deng *et al.*, 2010). NSCs in the V-SVZ produce immature neurons that migrate rostrally through the rostral migratory stream (RMS) and integrate into circuits of the olfactory bulb (Figure 2). These immature neurons produce two classes of olfactory bulb interneurons, granule and periglomerular cells (PGs), that modulate the information processing by the olfactory bulb projection neurons, the mitral and tufted cells. The olfactory bulb processes information about an animal's odor environment that is detected by olfactory sensory neurons in the nose and conveyed via mitral and tufted cells to other parts of the brain, including the cerebral cortex. Adult neurogenesis therefore modifies how olfactory circuits respond to odorants, thereby altering the organism's response to sensory stimuli. In this article, we focus on our understanding of the intrinsic and extrinsic factors that regulate neurogenesis within the V-SVZ and how these newly born neurons contribute to olfactory circuit function.

Neurogenesis in the V-SVZ and the SGZ share important similarities, and discoveries made in each system inform our understanding of the other. Adult NSCs in both the V-SVZ and SGZ share a number of features including an elongated, radial-like morphology and expression of the intermediate filament protein glial fibrillary acidic protein (GFAP). Both populations of adult NSCs exhibit a slow rate of turnover, producing a more rapidly dividing, intermediate progenitor cell (IPC) that generates neurons. Moreover, many of the same molecular signaling pathways regulate both adult NSC populations. For further reading on adult neurogenesis in the hippocampus, the reader is referred to a number of insightful reviews (see Further Reading).

Figure 1 Schematic of the adult mouse brain depicting the neurogenic regions. Adult neural stem cells (NSCs) reside in the ventricular-subventricular zone (V-SVZ), the epithelial layer lining the lateral ventricles (LV), and the subgranular zone (SGZ) of the hippocampal formation. Type B cells in the V-SVZ proliferate and generate intermediate progenitor cells which produce immature neuroblasts that migrate anteriorly through the rostral migratory stream (RMS) into the olfactory bulbs where new neurons incorporate into existing granule cell and periglomerular populations GCL, granule cell layer; GL, glomerular layer; M, mitral cell layer.

Figure 2 Olfactory circuit diagram. Odorant molecules are carried by air into the nose where they are detected by olfactory sensory neurons, each of which responds to a subset of odorants based on the expression of a single odorant receptor out of the hundreds present in most mammalian genomes. Axons of these sensory neurons convey information via the olfactory nerve (ON) into the central nervous system (CNS) where they terminate in the olfactory bulb in small globular structures termed glomeruli that are positioned in the superficial glomerular layer (GL). Each glomerulus receives input from sensory neurons expressing the same receptor. These sensory neuron axons form synapses with mitral (M) and tufted cells, each of which receives input from a single glomerulus and in turn conveys information to other regions of the brain. The information carried to the rest of the brain by mitral and tufted cells is highly influenced by their interactions with two other classes of neurons within the olfactory bulb. Periglomerular cells (PGs) surround a glomerulus and regulate the response profile of the cells forming synapses within that glomerulus. Granule cells are located in the core of the olfactory bulb in the granule cell layer (GCL). These neurons do not have axons, but send dendrites into the external plexiform layer (EPL), where they form reciprocal dendrodendritic synapses with dendrites of mitral and tufted cells.

Insights gained from the study of adult neurogenesis also impact our knowledge of developmental neurogenesis, despite inherent differences in these two epochs. Whereas adult neurogenesis involves incorporation of adult-born neurons into an existing circuit, developmental neurogenesis requires the *de novo* creation of these circuits. Nevertheless, many molecular pathways are shared between these two forms of neurogenesis. Moreover, much like developmental neurogenesis, adult NSCs in the V-SVZ comprise a heterogeneous population that produces morphologically and functionally distinct neuronal subtypes (Merkle *et al.*, 2014). Thus the adult NSCs of the V-SVZ provide a useful model system with which to study many of the fundamental principles of neurogenesis, including proliferation, cell specification, and regulatory pathways. Consequently, our understanding of both adult and developmental neurogenesis has been influenced by observations initially made in the other system. Neurogenesis in the developing brain is the subject of a number of excellent review articles (see Further Reading).

Historical Perspective

Evidence of mitosis in the mature CNS dates at least as far back as 1912, when Allen described mitotic figures in the brains of

4-month-old adult rats (Allen, 1912). Despite this report, the idea of adult neurogenesis remained largely unaccepted throughout much of the twentieth century. In the 1960s, Altman and Das published a series of reports describing the incorporation of radioactive thymidine ($[^3\text{H}]\text{-Thy}$) during DNA synthesis in the brains of mature mammals. Labeled cells were observed in the granular layers of the olfactory bulbs and hippocampal dentate gyrus of a number of adult mammalian species, including rats, guinea pigs, and cats (Altman, 1963, 1969; Altman and Das, 1965, 1967). These studies were largely dismissed due to the inability to determine the cellular phenotype of the labeled cells, and it was assumed that these cells were glia rather than neurons.

A major advance in the study of adult NSCs was the development and application of the thymidine analog bromodeoxyuridine (BrdU) to the study of proliferating cells in the mature CNS. Like $[^3\text{H}]\text{-Thy}$, BrdU is incorporated into DNA during synthesis. However, instead of detection by autoradiography, BrdU can be detected by immunohistochemistry. Therefore, double labeling with cell type-specific markers enabled lineage tracing of proliferating cells and subsequent identification of newly generated neurons in the brains of adult mammals. Using this strategy, investigators were able to identify BrdU-labeled neurons in the hippocampal dentate gyrus and the olfactory bulbs of various mammalian species, including rodents and primates (Cameron *et al.*, 1993; Gould *et al.*, 1997; Cameron and McKay, 2001), finally demonstrating unequivocally that neurogenesis persists in the mature CNS. In 1998, it was reported that postmortem human tissue from patients that had received a single BrdU infusion for diagnostic purposes also showed evidence of adult neurogenesis in the hippocampus (Eriksson *et al.*, 1998). Taken together, the overwhelming evidence for adult neurogenesis, and its relevance to humans, could no longer be ignored. A fundamental principle of neuroscience was overturned, reshaping our understanding of CNS function and its remarkable capacity for plasticity.

Identity of Adult NSCs

V-SVZ NSCs reside in a complex, multicellular niche that includes multiciliated ependymal cells, differentiated astrocytes, blood vessels, IPCs, and immature neuroblasts (Ihrle and Alvarez-Buylla, 2011). NSCs, known as Type B cells (Doetsch *et al.*, 1999), are rarely dividing neural precursors that express the intermediate filament protein GFAP (Doetsch *et al.*, 1999; Seri *et al.*, 2001; Garcia *et al.*, 2004). Type B cells are largely quiescent, dividing infrequently to produce rapidly dividing IPCs, or transit amplifying cells (Figure 3). Whereas Type B cells divide asymmetrically, producing one stem cell and one IPC, IPCs undergo symmetric cell division to produce two identical daughter cells, thereby amplifying the progenitor pool. Although IPCs are generally more restricted in their proliferation and differentiation potential than Type B cells, they retain multipotency *in vitro*, generating cells of the three major neural lineages – neurons, astrocytes, and oligodendrocytes (Doetsch *et al.*, 2002). *In vivo*, IPCs produce immature neuroblasts that ultimately mature into neurons (Figure 3). When isolated from the V-SVZ and grown in

Figure 3 Lineage relationship of adult neural stem cells (NSCs) and their progeny. Type B cells residing in the ventricular-subventricular zone (V-SVZ) express glial fibrillary acidic protein (GFAP) and possess a radial morphology. These cells undergo asymmetric cell division in which one daughter cell retains a stem cell identity, while the other cell acquires an intermediate progenitor cell (IPC) identity. IPCs are multipotent cells, capable of generating neurons, astrocytes, or oligodendrocytes.

culture, Type B cells display hallmark features of stem cells: self-renewal and multipotency. These cells form neurospheres that can be dissociated and passaged under clonal conditions, producing secondary and tertiary neurospheres (Reynolds and Weiss, 1992). Under differentiation conditions, neurospheres generate cells of the three neural lineages (Imura *et al.*, 2003). *In vivo*, Type B cells repopulate the V-SVZ following ablation of actively proliferating cells (Doetsch *et al.*, 1999). Moreover, lineage tracing using retroviral labeling and genetic fate mapping tools demonstrate that adult-generated neurons, astrocytes, and oligodendrocytes are derived from Type B cells (Garcia *et al.*, 2004; Menn, 2006). The adult V-SVZ therefore includes NSCs – the Type B cells – that can give rise to neurons.

GFAP expression has historically been used to identify mature, differentiated astrocytes, the major macroglial subtype in the CNS. Indeed, adult NSCs share a number of features with astrocytes, including a radial morphology and ultrastructural profiles, leading to their characterization as specialized astrocytes (Anthony *et al.*, 2004; Kriegstein and Alvarez-Buylla, 2009). Nevertheless, it is important to note that despite these shared features, adult NSCs are distinct from non-neurogenic astrocytes that are distributed throughout other regions of the brain. GFAP-expressing cells isolated from the adult V-SVZ exhibit neurogenic potential *in vitro*, whereas cells isolated from the adult cortex do not, even when grown in similar culture conditions (Laywell *et al.*, 2000; Imura *et al.*, 2006). There is some evidence that following an injury, reactive astrocytes in non-neurogenic regions such as the cortex can generate multipotent neurospheres *in vitro* (Sirko *et al.*, 2013), suggesting a latent neurogenic potential in non-V-SVZ astrocytes. The extent to which reactive astrocytes *in vivo* demonstrate neurogenic properties remains poorly understood.

During early development, neural precursor cells (NPCs) are derived from epithelial cells that initially line the neural tube. These neuroepithelial precursors exhibit a radial morphology, similar to that of adult NSCs (Kriegstein and

Alvarez-Buylla, 2009). Radial glia are bipolar cells, whose somata reside in the ventricular zone of the developing CNS, and whose processes make contact with both the ventricle and the pial surface, spanning the width of the developing cortex. Though once believed to be exclusively glial precursors, time lapse imaging of virally labeled radial glia in the embryonic mouse cortex demonstrated that radial glia divide to produce IPCs and cortical neurons (Noctor *et al.*, 2001). This suggests a lineage relationship between embryonic radial glia that produce cortical neurons, and Type B cells that produce neurons in the adult. Indeed, fate mapping studies in which radial glia are selectively labeled on the day of birth, postnatal day 0 (P0), reveal that Type B cells in the adult V-SVZ are directly derived from radial glia (Merkle *et al.*, 2004), further supporting the idea that adult NSCs are derived from radial glia in the developing CNS.

Cell Proliferation in the SVZ

As in development, proliferation of adult NSCs is tightly regulated by a number of molecular signaling pathways. Indeed, many of these pathways are shared by embryonic NSCs. Sonic hedgehog (Shh), an essential signaling pathway that regulates multiple processes including proliferation, patterning, and axonal pathfinding during embryonic development (Fuccillo *et al.*, 2006), is a key regulator of NSCs in the adult (Ahn and Joyner, 2005). Pharmacological and genetic disruption of Shh signaling in postnatal and adult brains leads to a reduction in neurosphere formation, as well as a reduction in proliferating cells in the V-SVZ *in vivo* (Palma *et al.*, 2005; Balordi and Fishell, 2007a,b). The reduction in proliferation in the V-SVZ persists, for at least 10 months following ablation of Shh signaling, ultimately depleting the pool of NSCs. The Notch signaling pathway, another key regulator of neurodevelopment, is active in Type B cells but not in IPCs (Imayoshi *et al.*, 2010). Genetic disruption of Notch signaling leads to a transient increase in the production of IPCs and immature neuroblasts, at the expense of Type B cells, pointing to a role for Notch signaling in the maintenance of adult NSCs in the V-SVZ. Whereas Shh and Notch signaling are constitutively active in adult NSCs under homeostatic conditions (Ahn and Joyner, 2005; Petrova *et al.*, 2013), activation of the Wnt signaling pathway in NSCs occurs only following injury or pharmacological depletion of actively dividing cells (Piccin and Morshead, 2011). This suggests that molecular regulation of NSCs is context dependent, enabling the nervous system to respond to local environmental conditions appropriately.

Olfactory stimulation is one factor likely to modify this local environment. Unilateral odor deprivation achieved by severing the olfactory nerve results in a loss of olfactory information to the deprived, ipsilateral olfactory bulb that leads to an increase in cell death on the ipsilateral side (Mandairon *et al.*, 2003). In contrast, measuring cell proliferation by BrdU incorporation reveals an increase in the number of BrdU-labeled cells on both the ipsilateral and contralateral sides. Since the increased proliferation on the contralateral side is not accompanied by cell death, these findings indicate that odor-dependent proliferation does not serve simply to compensate for apoptotic cell loss. Instead, the new cells are likely

to play an important role in a sensory system that is being remapped in response to an altered odor environment.

Neuronal Migration in the RMS

Neuroblasts generated within the rodent SVZ must migrate several millimeters rostrally to their destination in the olfactory bulb. The first stage of this migration takes place tangentially (i.e., parallel to the surface of the brain) in the RMS. The neuroblasts migrate along this path by crawling along each other in a process termed chain migration (Lois *et al.*, 1996). This homotypic mode of navigation stands in contrast to the more usual heterotypic migration in which developing neurons crawl along a cell of a different type (e.g., a radial glia) that serves as a scaffold. These neuroblasts do not only interact with each other, however, as they interact with other cells to travel to the olfactory bulb within tubes of astrocytic glial cells that are closely associated with blood vessels. The importance of these glia for supporting RMS migration is highlighted by the failure of neuroblasts to migrate rostrally in mice that do not form glial tubes due to lack of expression of the *Vax1* homeobox gene (Soria *et al.*, 2004). In these mice, the SVZ is expanded, the RMS does not form, and the olfactory bulbs are smaller than normal. However, *Vax1* null cells are able to migrate correctly if transplanted into wild-type tissue, indicating that the phenotype observed in the nulls reflects the disrupted migration scaffold.

Neuroblast guidance to the olfactory bulb is influenced by olfactory activity but, surprisingly, does not actually require this activity or even the olfactory bulb itself. Even when the olfactory bulb is surgically ablated, neuroblasts still join the RMS and migrate rostrally, where they accumulate before eventually dying (Kirschenbaum *et al.*, 1999). Instead of attractant cues that would pull the cells toward the olfactory bulb, the direction of migration is heavily influenced by repellant cues, including Slit proteins, that push the cells away from the SVZ in the same direction as the flow of the cerebrospinal fluid within the lateral ventricle (Nguyen-Ba-Charvet *et al.*, 2004; Sawamoto *et al.*, 2006). Several permissive cues along the path toward the olfactory bulb allow the rostral migration. These include integrin-mediated interactions with the extracellular matrix. Neuroblasts express $\alpha 6 \beta 1$ integrin, which binds to laminin. Interfering with integrin binding to laminin disrupts neuroblast migration while addition of peptides mimicking laminin will redirect these cells toward the exogenous source (Murase and Horwitz, 2002; Emsley and Hagg, 2003; Belvindrah *et al.*, 2007). Migration of the migrating cells is therefore influenced by molecular cues provided by their surrounding cells.

Despite receiving these cues from other cell types, the neuroblasts largely interact directly with each other as they migrate. These cells are distinguished by high expression of the protein NCAM (neuronal cell adhesion molecule) that has been posttranslationally modified through the addition of polysialic acid (PSA-NCAM). This molecule is critical for the chain migration as loss of total NCAM or removal of the PSA moiety leads to inefficient migration and a disorganized RMS (Chazal *et al.*, 2000; Hu, 2000). The rate of migration is sensitive to local levels of the neurotransmitter GABA, which is

nonvesicularly released by the neuroblasts themselves and modulated by uptake by the astrocytic glia surrounding the neuroblasts (Bolteus and Bordey, 2004). Neuroblast migration toward the olfactory bulb therefore requires a combination of repulsive and permissive cues and is regulated by interactions with the cells in the glial tubes.

Once the neuroblasts have reached the olfactory bulb, they cease their tangential migration and head toward the surface via radial migration. The switch from tangential migration in chains to radial migration as individual cells involves interactions with components of the extracellular matrix secreted by olfactory bulb cells, including the proteins tenascin-R and reelin (Hack *et al.*, 2002; Saghatelian *et al.*, 2004). Interestingly, the expression of tenascin-R in the granule cell layer is regulated by odor exposure, suggesting that differential tenascin-R expression in more active olfactory pathways may guide neuroblasts to sites of need within the olfactory bulb.

Neuronal Differentiation in the Olfactory Bulb

The adult-born cells differentiate into their final neuronal phenotype as they join existing circuits in the olfactory bulb. Depending on several factors, including where in the stem cell niche the original progenitor resided, these cells can adopt the fate of periglomerular or granule cells. PGs surround and regulate the response profiles of glomeruli – acellular, spherical balls of neuropil where synaptic contact between the sensory neurons and the mitral and tufted cells occurs. PGs can be subdivided into populations based on their molecular phenotype including the expression of specific calcium-binding proteins (e.g., calbindin vs. calretenin) or the neurotransmitter they release (GABA vs. dopamine). Granule cells, located in the core of the olfactory bulb, are GABAergic neurons that mediate interactions between mitral and tufted cells and can modulate the synchronicity of the output of these neurons. The position of a granule cell (superficial vs. deep) correlates with both its molecular phenotype as well as the cells with which it forms synapses in the external plexiform layer. Periglomerular and granule cells are therefore critical components of the olfactory bulb circuits that process olfactory information.

Adult neurogenesis generates periglomerular and granule cells of all known molecular phenotypes (Whitman and Greer, 2007a). The final identity of these neurons is based largely on the positional identity within the V-SVZ of the NSC from which a given neuron is derived (Young *et al.*, 2007). Specifically, Type B cells at different locations along the dorsoventral axis of the V-SVZ give rise to distinct populations of olfactory bulb interneurons. A major regulatory signaling molecule guiding cell fate is Shh signaling, in addition to its previously discussed role in maintaining the adult NSC pool. Shh signaling is most active in Type B cells localized in the ventral V-SVZ (Ihrle and Alvarez-Buylla, 2011; Petrova *et al.*, 2013). Genetic fate mapping studies have shown that ventral V-SVZ stem cells primarily produce deep granule cell neurons in the olfactory bulb (Merkle *et al.*, 2007, 2014). Targeted deletion of Shh in transgenic mice leads to a redistribution of adult-generated olfactory bulb neurons, with a reduction in the number of deep granule layer neurons and a concomitant

increase in the production of superficial granule cells (Ihrle and Alvarez-Buylla, 2011). PGs are also affected by disruption of Shh signaling. Specifically, the production of calbindin-positive periglomerular neurons is reduced by 90% following disruption of Shh signaling. Moreover, ectopic activation of Shh signaling in NSCs localized in the dorsal V-SVZ leads to increased production of deep layer granule cells localized in the olfactory bulb. Taken together, these observations point to Shh signaling in Type B cells as necessary and sufficient to specify the fates of adult-generated olfactory bulb neurons.

Newly generated granule cells exhibit stereotyped morphologies as they differentiate (Petreanu and Alvarez-Buylla, 2002; Carleton *et al.*, 2003; Whitman and Greer, 2007b). During both tangential and radial migration, they appear poorly differentiated with an elongated cell body and both leading and trailing processes. Upon reaching their final destination, the cell body becomes round and there is only a single apical process that will eventually be the primary dendrite. At this point, these neurons receive their first synapse: excitatory synapses formed by axons of other cells on the cell body of the new neurons. These synaptic inputs are thought to modulate granule cell survival and differentiation by providing information from the odor environment as well as from other regions of the brain. The majority of the second wave of synapses are from inhibitory GABAergic inputs. As the nascent dendrite grows into a full dendritic arbor, GABA stabilizes both dendritic growth cones and recently formed dendrite branches. Although the signal transduction elements involved in this dendritic outgrowth remain to be worked out, CREB phosphorylation is increased during this period. Dendritic arbor elaboration is followed by the formation of dendritic spines, which are indicative of the reciprocal dendrodendritic synapses characteristic of mature granule cells that have integrated into local synaptic circuits. Synaptic integration of newborn granule cells thus follows a defined pattern in which these cells first receive synaptic input before providing synaptic information to other cells.

Potential Functions of Adult Neurogenesis

The reason that neurogenesis is maintained specifically in particular regions of the vertebrate brain is unclear. There is, however, an association between adult neurogenesis and learning and memory. Songbirds exhibit a correlation between song learning and adult neurogenesis. Targeted cell death of neurons that are normally replaced in songbirds leads to deterioration of a previously learned song (Scharff *et al.*, 2000). In rodents, learning tasks that require hippocampal function increase the survival rate of adult-born neurons while loss of these neurons impairs performance on hippocampal-dependent tasks (Saxe *et al.*, 2006). In the olfactory system, the young neurons are subject to intense competition to survive such that well over half of the new cohort will die not long after arriving in the olfactory bulb (Petreanu and Alvarez-Buylla, 2002; Winner *et al.*, 2002). Whether a newly born cell survives to join an olfactory bulb circuit is heavily influenced by olfactory experience as well as signals from other regions of the brain (Rocheffort *et al.*, 2002; Mandaïron *et al.*, 2006). Intriguingly, pairing an odorant with a learning paradigm

increases the survival of newborn neurons while the same odor exposure that is not paired with learning has no detectable effect on cell survival (Alonso *et al.*, 2006). Similarly, pregnancy causes an increased rate of neurogenesis and neuronal survival, effects that are mediated through the hormone prolactin (Shingo *et al.*, 2003). The incorporation of young neurons into the existing olfactory circuits therefore is influenced by a variety of factors including the odor environment and the physiological state of the individual.

One reason for incorporating new neurons into olfactory circuits may be that odor responses of newborn neurons are distinct from those of mature neurons. As neurons differentiate and go through the period of rapid synaptogenesis described above, they also exhibit heightened responses to odorants. One indirect measure of neuronal activation is assaying for stimulus-dependent expression of immediate-early genes, which are upregulated in neurons that have recently been activated. By assaying immediate-early gene expression after odor exposure, the population-level response to odor of young neurons exceeds that of the population of mature neurons (Carlén *et al.*, 2002; Magavi *et al.*, 2005). Consistent with this, monitoring responses of individual neurons show that they become more selective as they mature – i.e., each neuron responds to fewer olfactory stimuli with age (Livneh *et al.*, 2014). Further, these young neurons are particularly plastic in their synaptic responses, which likely reflects the high ratios of NMDA glutamate receptors to AMPA glutamate receptors as compared to that seen in mature neurons (Carleton *et al.*, 2003). These findings suggest that the young neurons are in what is essentially a critical period, analogous to the period of time in which organisms are particularly susceptible to environmental influences. Indeed, activation of PGs during the period of robust plasticity alters the response profiles of the same cells once they have matured as compared to those cells that were not stimulated during the same period (Livneh *et al.*, 2014). Thus, incorporation of newborn neurons into olfactory circuits shapes the function of those circuits and does not merely replace cells that were previously present that had been lost to cell death.

Potential Applications

The discovery of cells that continue to proliferate and give rise to new neurons in the adult CNS not only changed the way we understand the brain, but also raised hopes that these findings would impact our treatment of disorders involving a loss of neurons – whether from surgical resection such as in cancer patients or neurodegeneration such as in Parkinson's disease patients. One possibility to treat such patients would be to redirect the cells generated in the V-SVZ to another part of the brain; however, it seems unlikely that these cells would be relevant to other circuits and thus might not be therapeutically beneficial. Another potential approach with greater flexibility is the transplantation of neurons generated from induced pluripotent stem cells (iPSCs). Detailed knowledge of the molecular factors that guide the differentiation of NSCs *in vivo* will enhance the diversity of cells that can be generated from iPSCs *in vitro*. Finally, recent evidence suggests that other regions of the brain in addition to the SGZ and V-SVZ may harbor latent

neurogenic capacity (Magnusson *et al.*, 2014). Inducing neurogenesis from these other progenitors may also alleviate some of the symptoms that arise when large numbers of neurons are lost from the adult brain. Though the study of these questions is still in the early stages, the potential therapeutic implications, particularly of the iPSCs, are very exciting.

Conclusion

In this article, we have focused on neurogenesis in a specific context – the generation in the adult rodent brain of neurons that reside within olfactory circuits. The study of this phenomenon, which had been erroneously thought to be impossible, has offered great insights into how the vertebrate brain works. Indeed, this initially controversial discovery has opened up new lines of thinking about the cellular basis of sensory perception as well as learning and memory. The findings from the study of adult neurogenesis have also informed our understanding of *in vivo* developmental neurogenesis and *in vitro* artificial neurogenesis during iPSC differentiation. Importantly, our understanding of adult neurogenesis has arisen from approaches that span multiple scales from the molecular up through the behavioral. The study of this phenomenon thus serves as an example for how to successfully integrate approaches in order to address a complex biological problem.

HORIZONTAL INTEGRATION: NETWORKS

Understanding of ‘Networks’ *In Vitro* and/or *In Vivo*

Introduction

In this article we shall explore the requirement for and tools relevant to the understanding of networks in varying biological contexts from cellular (*in vitro*) to living organisms (*in vivo*). We will focus on molecular networks and pay particular attention to protein-signaling networks. To avoid jumping from one technological wonder to the next we will use the example of cancer, and in particular tumor biology, as a constraint set to describe the need to understand networks in different biological contexts and how comprehensive and large-scale quantitative technologies, combined with sophisticated computational modeling, is crucial for both basic biology and cancer therapy. Ever since its conceptual discovery as early as 3000 BC in ancient Egypt (Society, 2012), cancer has been eluding major scientific breakthroughs in terms of finding a cure. Despite large-scale efforts such as the ‘War on Cancer’ (Hanahan, 2013) in the twentieth century, and estimated yearly research budgets as high as 14 billion Euros worldwide (Eckhouse *et al.*, 2008), the disease continues to have a devastating effect on people’s health, with often lethal consequences. For cancer patients in the United States alone, the financial burden of healthcare ranges was estimated at US\$88.7 billion in 2011. In this article, a brevilouquent overview of cancer will be provided, focusing mainly on conceptual challenges that have arisen over the years and scientific approaches that have been developed in an attempt to tackle some of the many aspects of the disease. Specifically, the significance of moving from a pathway-centric interpretation of cellular signaling toward a more global signaling network approach will be reviewed and discussed. Next, new technological platforms from which to study integrated biological functions will be introduced, with a special focus on Network Biology and technologies fundamental to this such as mass spectrometry (MS), next-generation sequencing (NGS), siRNA-based high content screening (HCS), and computational modeling to allow the integration of different types of data. Together, it is envisioned that these genome-scale technologies will provide quantitative data that can form the basis of computational integrative modeling and biological forecasting to predict cellular behavior in both *in vitro* and *in vivo* biological contexts.

The Complex Nature of a Disease and Its Underlying (*In Vitro*) Molecular Networks

While extensive strides have been made in terms of defining biological characteristics that drive a tumor cell toward

malignancy, there is still great debate about the precise underlying causes at each stage. As will be discussed throughout this article, several biological phenomena may be fundamental to all human diseases, ranging from mutations occurring in the genome of the diseased cells (Burrell *et al.*, 2013; Stephens *et al.*, 2012; Vogelstein and Kinzler, 2004; Vogelstein *et al.*, 2013; Stratton *et al.*, 2009), through epigenetic regulation of DNA transcription (Dawson and Kouzarides, 2012; Feinberg and Tycko, 2004), to dysregulated protein network dynamics (Cox and Mann, 2007; Creixell *et al.*, 2012; Pawson and Hunter, 1994; Pawson and Kofler, 2009; Tan *et al.*, 2009; Taylor *et al.*, 2009; Taylor and Wrana, 2012; Vidal *et al.*, 2011; Pawson and Linding, 2008). Whilst each of these may contribute individually, it is likely that a combination of these aspects is what ultimately drives cancer and adds to the complexity of understanding a given disease phenotype. For example, it is known that more than 50% of human melanomas contain an activating mutation in the BRAF kinase gene, where the valine in amino acid position 600 is substituted with a glutamate (BRAF V600E), which, through structural effects, renders the kinase constitutively active (Davies *et al.*, 2002). This permanent kinase signaling results in a constitutive activation of the Raf to mitogen-activated protein (MAP) kinase pathway, significantly increasing the rate of mitogenesis of these cells (Davies and Samuels, 2010). While inhibition of this mutant-specific variant of BRAF often results in a temporary response to treatment in the clinic (Flaherty *et al.*, 2010), resistance ultimately develops as the signaling networks normally utilizing the BRAF kinase pathway are rewired to circumvent the BRAF inhibition (Poulidakos and Rosen, 2011; Wagle *et al.*, 2011). Currently, the use of additional inhibitors to subsequently target the rewired cellular signaling networks is being investigated, with some initial success (Lito *et al.*, 2012). This is a prime example of how mutations at the genome level exert their effect at the protein-signaling level, and underlines the importance of investigating both genomic and proteomic aspects of a cell when trying to gain a thorough understanding of a given disease phenotype. In addition, while proteins are the cell’s functional effectors and almost exclusively the targets of small-molecule inhibitors and antibodies, understanding the underlying genomes can help pinpoint appropriate protein targets and aid in elucidating molecular mechanisms of a particular disease. Especially considering the fact that “no single gene defect ‘causes’ cancer” (Vogelstein and Kinzler, 2004), understanding how proteins interact with one another in a signaling network

through proteomic analysis can help prioritize which mutations may act in a coherent manner and should be further investigated in combination for therapeutic purposes (Yaffe, 2013). While the complexity is extremely high at the genomic level, given the similar phenotypic states of cancer cells (increased proliferation, migration etc.), the complexity might be better understood at the protein-signaling network level. In other words, while the mutational landscapes might differ greatly between tumors, their functional impact on the signaling networks within the cell might be less varied, thereby eliciting a similar phenotype. This underlines the need for assessing the impact of mutations at the protein level (Creixell *et al.*, 2012).

Tumor Microenvironment – A Biological Reality that Can Only Be Understood *In Vivo* and Using Global Integrative and Quantitative Technologies

A biological aspect this section will briefly touch upon is the role of the microenvironment, as extensive evidence has demonstrated that it is not only the tumor cells themselves which decide the fate of pathogenesis, but rather that it is the complex interplay of the tumor cells with their surrounding microenvironment and other cell types contained therein (see Figure 1; Hanahan and Weinberg, 2011). In healthy tissue, the stroma (consisting of extracellular matrix (ECM) and other cells such as endothelial cells, fibroblasts, etc.) is generally considered the supportive structure of a given tissue or organ,

and maintains a natural barrier against tumorigenesis. When tumor cells appear however, this process initiates a cascade of changes, often resulting in the stroma becoming an environment that supports cancer progression. This involves, amongst others, the activation of fibroblasts and matrix remodeling, and additionally, microenvironmental stimuli such as hypoxia and acidity, and growth factors will vary within a tumor, giving rise to additional heterogeneous cell populations, each adapted to their specific microenvironment. These microenvironmental factors are likely to affect both the signaling network states of tumor cells contained within, and may even select for specific DNA mutations that give certain subpopulations an evolutionary benefit depending on their surroundings.

A particular cell type that has been associated extensively with cancer progression, and thereby merits scientific investigation, is the cancer-associated fibroblast (CAF). Where normal fibroblasts typically have a suppressive effect on tumorigenesis (Dotto *et al.*, 1988), CAFs can significantly enhance tumor progression (Orimo *et al.*, 2005). They distinguish themselves from normal fibroblasts by displaying increased proliferation levels, enhanced cytokine secretion, and elevated ECM production and increased contractility (Polanska and Orimo, 2013). These differences result in extensive tissue remodeling, predominantly around the tumor cells, driven extensively by, for example, elevated expression of matrix metalloproteases, pro-angiogenic factors, matrix cross-linkers such as lysyl oxidase (LOX) and transglutaminases, and growth factors (Bergers *et al.*, 2000; Erler *et al.*, 2006). The clinical relevance of CAFs has been established in several ways. For example, the abundance of CAFs has been

Figure 1 Schematic representation of the key cellular components of the tumor microenvironment and cellular components contributing to tumor heterogeneity. In invasive and metastatic tumor microenvironment, there is an increase in number of invasive cells, contributing to the overall tumorigenesis. Reproduced from Hanahan, D., Weinberg, R.A., 2011. Hallmarks of cancer: The next generation. Cell 144, 646–674.

shown to be predictive of prognosis for both breast and pancreatic cancer (Fujita *et al.*, 2010; Yamashita *et al.*, 2012). Additionally, elevated matrix metalloprotease levels, which are secreted both by tumor cells and CAFs, have also been linked with increased tumor aggressiveness and poor prognosis (Vihinen and Kahari, 2002). Furthermore, CAFs have been associated with emerging treatment resistance (Meads *et al.*, 2009). For example, in BRAF(V600E) cell lines, cocultured with CAFs, BRAF inhibition was overcome by secreted hepatocyte growth factor (HGF), which elicited increased phosphorylation of MET, a cognate receptor of BRAF (Straussman *et al.*, 2012; Wilson *et al.*, 2012). This has also been observed in patients, where HGF expression levels positively correlated with reduced drug treatment response (Straussman *et al.*, 2012). These studies highlight the importance of studying cancer cell signaling within the appropriate context, as the *in vivo* relevance of *in vitro* derived results will be limited.

To add to the complexity, the influence of the micro-environment on tumorigenesis is a bidirectional process. As was recently shown by Barker *et al.*, LOX-like 2 (LOXL2) is an enzyme secreted by tumor cells, which in turn activates the CAFs through integrin-mediated focal adhesion kinase activation. By blocking LOXL2, the authors reduced the activation of stromal host cells, and significantly decreased tumor cell invasion (Barker *et al.*, 2013). Similarly, Cox *et al.* (2013) investigated the effect of the microenvironment on the metastatic potential of a tumor. They found that the expression of LOX, an enzyme that catalyzes the covalent cross-linking of collagen I and which has been implicated in cell invasion and malignant progression (Bissell and Labarge, 2005; Erler *et al.*, 2006), is "favourable to colonization and growth of metastasising tumor cells" (Cox *et al.*, 2013). By specifically blocking LOX activity using an antibody, they were able to reduce the ECM modifications that normally have an enhancing effect on tumor cell survival and metastasis. As LOX is secreted from the 4T1 cell line used in the study, this elegantly highlights the complex bidirectional interplay of tumor cells and their surrounding microenvironment. Not only does the targeting of proteins secreted by the tumor cells seem like a viable therapeutic strategy though, as work by Luga *et al.* (2012) demonstrated that targeting CAF-secreted exosomes (using Cd81-specific siRNAs) has a beneficial effect on specifically suppressing lung metastases in a breast cancer model. Combined, these *in vivo*-derived results suggest that targeting both the tumor cells and surrounding stromal cells are attractive therapeutic strategies, and that more extensive investigation is merited to uncover additional molecular mechanisms driving tumorigenesis, both in tumor and their surrounding stromal cells.

In summary, these first two aspects underline the importance of moving away from viewing a tumor (the biological system) as a homogeneous population that can be treated as a whole, as it is evident that the complexity is much larger than initially assumed. Only by biologically characterizing the contribution and integration of individual components that make up a tumor, both separately and collectively, and understanding how they can be therapeutically targeted, it is likely that cancer research will start fulfilling its promise of successful targeted therapies. In other words understanding how the underlying molecular networks operate in an integrative manner to control the tumor's evolution and interaction with the host organisms

requires studies of such networks at different biological context levels ranging from cell culture (*in vitro*) to animal models (*in vivo*) and eventually in patients. The critical goal of network biology is thus to provide predictive capabilities in these more and more complex environments. Deriving computational models that can perform such forecasting of how cells react to cues/environment even in one context is challenging but vital for our basic understanding of how information is processed in biological systems.

To drive the message home loud and clear, we shall end this intermezzo of cancer biology and why it is one of the greatest challenges to our understanding of molecular networks and how they process information, by revisiting the topic of cancer metastasis. Arguably one of the most complex biological processes we know of, this process is a highly complex graph-like evolutionary path that many cancer cells undertake in a complex interaction with other cells and the host tissues and immune defense. This is not only a daunting task to grasp from a 30 000 feet view, but even more so at its primordial state in terms of our understanding of the cellular signaling networks involved.

Cancer Metastasis – A Showstopper for 1-Context-Only Studies/Theories

As part of the cancer evolution, the cascade of tumorigenesis often ends at the metastatic stage, at which point the tumor cells, having acquired the necessary mutations and other phenotypic traits (e.g., invasiveness, enhanced proliferative capacity, etc.), are able to colonize other organs within the body. This spread of cancer cells to other, often vital organs, is responsible for 90% of all cancer-related patient mortality, and, if targeted successfully, represents the hallmark with most therapeutic potential (Gupta and Massague, 2006). In this section, we will explore some of the underlying biological principles, challenges associated with characterizing metastatic cells and possible directions for gaining a better understanding of how to tackle metastatic disease.

The process of metastasis is often classified into a series of basic biological events, which are portrayed in Figure 2 (Erler and Giaccia, 2008). The steps involve (1) local invasion, (2) intravasation (entry into the bloodstream), (3) extravasation (exit from the bloodstream), and (4) colonization of the distant tissue, from which further metastases can also be spawned (Chambers *et al.*, 2002; Fidler, 2003). While each of these steps represents a potential opportunity for therapeutic intervention to varying degrees, it is important to consider the origin of these traits and how tumor cells obtain these capabilities, as this may lay the foundation for successful prevention; this will be further explored in the next section. As previously explained, the concept of cancers consisting of a heterogeneous population of tumor and stromal cells has now been widely accepted, each cell lineage contributing to the development process. Furthermore, research conducted in the last decade has suggested that several oncogenic events during cancer development may contribute to the evolution of tumors. Especially the ability to resist growth suppression and bypass DNA-damage-checkpoints are critical properties, as this allows for the generation of genomic instability (Hernando *et al.*, 2004; Maser and DePinho, 2002; Puc *et al.*, 2005;

Figure 2 The process of metastasis, depicting the different biological processes tumor cells must undergo to successfully colonize distant tissue sites. Adapted from Erler, J.T., Giaccia, A.J., 2008. Chapter 3: Critical Steps in Cancer Metastasis. In *Clinical Oncology*.

Gorgoulis *et al.*, 2005). Particularly in the case of colorectal cancer (CRC) pioneering work by Vogelstein and colleagues was able to show that colorectal tumorigenesis largely relies on the linear accumulation of key mutations (Fearon and Vogelstein, 1990). Through this, tumor cells are exposed to many evolutionary paths, some of which may give a specific subpopulation, for example, a fitness advantage or the phenotypes required for metastatic progression. Additionally, the genetic and phenotypic diversity that thereby exists within a tumor may also explain why, despite millions of cells being shredded by a tumor into the bloodstream every day, only a very small subset of these will successfully colonize distant tissue (Fidler, 1970; Kim *et al.*, 2004; Luzzi *et al.*, 1998). Part of the reason for this high attrition rate of distant organ colonization is the fact that healthy tissue generally provides an inhospitable environment for invading tumor cells, requiring a significant level of resilience to exist in metastatic tumor cells to overcome this. As originally postulated by Paget (1889), the spread of metastasis is dependent on both the primary tumor (the 'seed') and the distant site (the 'soil'). For an extensive review, the reader is referred to (Fidler, 2003), but it is interesting to note that the metastatic progression has indeed been shown to depend on both the primary and secondary tissue sites (Gupta and Massague, 2006; Nguyen *et al.*, 2009). Thus, it becomes clear that it is beneficial for a tumor to contain specific subpopulations of tumor cells, all bearing different pheno- and genotypes, allowing the successful growth of the primary tumor and distant metastases in their respective environments. Pioneering work conducted by Fidler (1970) demonstrated that within a tumor, rare clones exist that, through evolutionary processes, acquired the necessary properties which allowed them to drive metastatic progression. Later work revealed that highly metastatic subpopulations display a higher level of genetic mutability than their non-metastatic counterparts from the same tumor, in addition to biological heterogeneity being observed both within a single metastasis ('intra-lesional' heterogeneity) and among different metastases ('inter-lesional' heterogeneity), which supports the link between metastasis and genetic

instability/evolution (Fidler, 2003). Overall, these results seem to suggest that cancer progression is a function of heterogeneous cell populations being driven to evolve through sequential environmental stimuli and pressures (Gupta and Massague, 2006).

For these reasons, it is important to consider the underlying molecular processes which facilitate metastatic progression and the above-mentioned biological properties. Moreover, obtaining a comprehensive understanding of which proteins seem to play a fundamental role, and in particular which stages of tumorigenesis, is of critical importance, as they may each pose possible therapeutic targets. *In vitro* studies provide good utility for studying metastatic processes in isolation and laying the foundation for the molecular landscapes potentially involved; however, given the cellular interactions required for the process of metastasis, studying the process *in vivo*, while experimentally challenging, is imperative to increase the chances of therapeutic success. Kinases have been shown to be involved in many metastasis-promoting cell behaviors such as cell proliferation, migration, survival, and invasion (Baker *et al.*, 2013a,b; Brognard and Hunter, 2011; Cox *et al.*, 2013; Criscuolo *et al.*, 2005; Engelman *et al.*, 2007; Hiratsuka *et al.*, 2002; Lee *et al.*, 2012; Regan Anderson *et al.*, 2013; Jorgensen *et al.*, 2009), and thereby form attractive therapeutic targets (Davis *et al.*, 2011; Fedorov *et al.*, 2010; Janne *et al.*, 2009; Karaman *et al.*, 2008). In fact, it has recently been shown that kinases are the most frequently mutated proteins in tumors, underlining the potential therapeutic implications they represent (Lin *et al.*, 2007; Wood *et al.*, 2007). Given the diversification that tumor cells undergo throughout metastatic progression, and the ubiquitous involvement of kinase signaling in cellular signal processing (Linding *et al.*, 2007; Pawson and Kofler, 2009; Macurek *et al.*, 2008; Yaffe and Cantley, 1999), it is expected that kinase activities will be altered during this process as well. Therefore, obtaining a global overview of which kinases and other proteins are dysregulated during tumorigenesis is of great importance, also considering the plethora of inhibitors available for this group of proteins.

Networks in Cancer

Principles of Network Biology

The last decade has seen a considerable shift of moving away from a 'one drug, one target' approach (Beadle and Tatum, 1941), as, especially in the case of complex diseases such as cancer, deploying highly specific compounds targeting a single molecular entity has led to extensive treatment failure (Chandarlapaty *et al.*, 2011; Huang *et al.*, 2007b; Schoeberl *et al.*, 2009). Traditionally, the single-target approach focused primarily on individual 'pathways' that were found to have been dysregulated in disease. However, it has become increasingly clear that the proteins making up a specific pathway have many interactions outside their respective pathways, and it is therefore imperative to gain a better understanding of how individual pathways are assembled into higher order networks (Vidal *et al.*, 2011). This aspect is further highlighted by the genetic complexity and heterogeneity of tumors, as the mutations spanning a large multitude of proteins will have a different effect on the protein dynamics, yet still result in similar disease phenotypes. In other words, several genotypes can give rise to the same phenotype, while a single genotype can also give rise to several phenotypes, depending on the cellular context. These 'genotype-to-phenotype' relationships are one of the fundamental aspects the field of network biology is aiming to resolve, as, being the cellular effectors, protein signaling plays a critical role in defining the link between genotype and phenotype (see Figure 3; Pawson and Linding, 2008; Vidal *et al.*, 2011; Cox and Mann, 2007; Creixell *et al.*, 2012; Gstaiger and Aebersold, 2013; Bakal *et al.*, 2007). Rather than characterizing signaling pathways in isolation, it is therefore of vital importance to comprehensively measure genome-wide protein levels within the cell, as this allows the characterization of their global network structure and

dynamics and how genomic information is propagated toward cellular phenotype (Nurse, 2003; Vidal, 2009; Vidal *et al.*, 2011; Taylor and Wrana, 2012; Gstaiger and Aebersold, 2009). Additionally, it has been proposed that it is not only individual protein species that make up a signaling network that can be therapeutically targeted; instead the structure and dynamics of a particular signaling network poses a powerful drug target by modulating the information flow through such a network (Pawson and Linding, 2008). This was further exemplified by work demonstrating that cells utilize the same protein network components for different cellular responses, and instead alter the network utilization of these to elicit a specific response. This highlights the importance of identifying how cellular networks are deployed specifically in a given disease condition, in order to be able to target the dynamics through disease-specific perturbations (Miller-Jensen *et al.*, 2007; Huang *et al.*, 2007a,b). Furthermore, by measuring global protein dynamics within the cell, a more comprehensive interrogation of how the effect of a perturbation affects the signaling network as a whole can be achieved. The importance of this was first elegantly demonstrated through seminal work by Janes *et al.* (2005). The authors investigated whether the phosphorylation state of Jun-activate kinase (JNK) was indicative of pro-apoptotic or anti-apoptotic activity, and concluded that the phosphorylation state alone did not suffice to characterize the phenotypic effect of JNK. Instead, they were able to show that activation of JNK could lead to both apoptosis and proliferation, and that the outcome was dependent on the prior signaling network state at the time of activation. This landmark study conclusively proved that studying the activity of a single protein in isolation is not sufficient to accurately characterize its cellular role, and rather, that the contextual network it is operating within also needs to be interrogated in order to obtain a correct readout. Similarly, utilizing this contextual information allows the characterization of the signaling network rewiring that occurs in response to a perturbation, in order to target these altered network states with an additional perturbation. The power of this type of approach was demonstrated by Lee *et al.* (2012), where they were able to greatly increase the level of apoptosis in breast cancer cells by designing a time-staggered combination treatment in a data-driven way.

In addition to protein dynamics (i.e., expression levels) altering cellular phenotype, extensive research has demonstrated that posttranslational modifications (PTMs) such as phosphorylation also play a crucial role in controlling cellular behavior (Jorgensen and Linding, 2008; Jorgensen *et al.*, 2009; Lemmon and Schlessinger, 2010; Pawson and Kofler, 2009). The importance of phosphorylation is further supported by the fact that by 2010, 149 inhibitors targeting 42 kinases (the 'writers' of phosphorylation modifications) have been subjected to clinical testing, highlighting the therapeutic potential of interfering with PTM signaling (Fedorov *et al.*, 2010). A significant challenge with deciphering phosphorylation-based signaling, however, is the derivation of kinase-substrate interactions; due to the highly transient nature of kinase-substrate interactions, it is inherently challenging to experimentally determine which kinase(s) is responsible for a given phosphorylation site. Therefore, generally, a combination of experimental and computational analysis is required,

Figure 3 The genotype-to-phenotype relationship, with protein-signaling networks playing a critical role as a link between the two. Mutations (indicated with a red star) at the DNA level can affect signaling events at the protein level, hence having the potential to alter molecular signaling networks.

to which end algorithms such as NetPhorest and NetworKIN have been developed (Linding *et al.*, 2007, 2008; Miller *et al.*, 2008; Horn *et al.*, 2014). These algorithms allow, based on both experimentally determined linear motif preferences of kinases and their network contextual information, to predict which kinases are likely candidates for experimentally observed phosphorylation sites. The linear motifs (specific sequence preference around the phosphosite) are predicted by NetPhorest, and STRING (a protein–protein association database) adds the network contextual information on whether or not the kinase and substrate protein (containing the phosphorylation site) are known/predicted to interact *in vivo*. Combined, they are amongst the most comprehensive and accurate algorithms currently available compared to previously published frameworks (Blom *et al.*, 2004; Obenauer *et al.*, 2003; Wong *et al.*, 2007; Xue *et al.*, 2005). These algorithms have high utility for studying posttranslational signaling when combined with cellular perturbations and global quantitative phosphoproteomics data, to pinpoint key kinases which may be fundamental to a given cellular phenotype.

Tools to Study Networks at Multiple Levels of Biological Complexity

In order to facilitate comprehensive sampling of the genotype-to-phenotype relationship, it is imperative that we can measure as many of the underlying properties (e.g., genome, epigenome, metabolome, proteome, and cellular phenotypes) as possible, in a global, unbiased manner. Subsequently, these different biological aspects can be integrated in order to establish causal relations that may exist between them. From a practical point of view, this generally means that large experimental and computational infrastructures are required, to allow the generation and analysis of the required large-scale datasets in a timely fashion. We will now briefly explore some of these technologies in the light of trying to decipher cellular signaling in cancer using a Network Biology approach.

In order to systematically assess the genomic landscapes within a tumor, NGS of DNA or RNA is the method of choice, as it allows the determination of sequence variants either within the complete genome, or only the protein-coding exome. This type of analysis results in a complete view of the genomic landscape that exists within a particular cellular context, and allows one to begin inferring which genes might play a role in a particular disease phenotype without any prior knowledge (Stratton *et al.*, 2009; Vogelstein *et al.*, 2013). With the significant decrease in costs associated with having a genome sequenced over the last few years, more and more laboratories obtain the capability of conducting such experiments, which has led to an explosion in publications analyzing diseased genomes (Network, 2011; Forbes *et al.*, 2010; Pleasance *et al.*, 2010; Rapley *et al.*, 2009; Stephens *et al.*, 2009). Nevertheless, a direct therapeutic impact that was expected to arise from these analyses has been rather limited (Yaffe, 2013). One fundamental shortcoming of using genomic data alone is the fact that it does not allow interpretation of how these mutations affect, or are utilized by, the cellular signaling networks. In other words, additional experiments are required for deducing which mutations have a functional

impact, and are thereby functionally related to the disease phenotype (Torkamani and Schork, 2009). For example, detecting a mutation at the DNA level does not guarantee that the mutation actually is expressed at the protein level, where it could exert an effect. Additionally, it may not be the mutations themselves which have a phenotypic effect, but rather, in case of kinases being affected by a mutation, the dysregulated phosphorylation-based signaling or network rewiring that is caused by the mutation (Creixell *et al.*, 2012). This underlines the need for actually being able to assess the protein dynamics of both the mutant proteins and their non-mutated network partners, and the dynamic phosphorylation networks which may be altered due to the genomic alterations. Additionally, the functional effect of a given mutation may only be apparent under specific cellular conditions, underlining the need for studying cellular behavior in response to several stimuli (e.g., growth factor stimulation, starvation, hypoxia, or stromal cocultures) or under varying cellular contexts (e.g., 2D/3D *in vitro* cultures and *in vivo* animal models).

Recent developments in the field of MS have led to major improvements of what portion of the expressed proteome can be measured in a single experiment. Currently, it is possible to simultaneously detect and quantify the protein levels of almost the complete proteome and several tens of thousands of phosphorylation events (Beck *et al.*, 2011; Geiger *et al.*, 2012; Munoz and Heck, 2011; Nagaraj *et al.*, 2011; Wisniewski *et al.*, 2009; Bodenmiller *et al.*, 2007; Bodenmiller and Aebersold, 2010; Sharma *et al.*, 2014). Quantitative technologies such as SILAC or dimethyl labeling allow the direct comparison of specific proteins or, for example, phosphorylation sites between one or several proteomes, in order to determine the dynamic regulation thereof (Boersema *et al.*, 2009; Ong and Mann, 2007). Their principle is based on utilizing stable isotopes to introduce a small mass difference into the peptides that exist within a given sample, which allows the mixing of samples. This mass difference is large enough for a high resolution mass spectrometer to determine the sample of origin, and through direct comparison of the peptide intensities originating from the respective samples, enables direct quantitation of these peptides. As samples are mixed in the early stage of sample preparation, any difference in intensity will most likely be due to a biological effect rather than a technical artifact. If used in combination with appropriate experimental design, this type of quantitative analysis enables the in-depth characterization of the dynamic regulation of protein signaling after a given perturbation such as inhibitor treatment, growth factor stimulation, mutations, or altered growth conditions (e.g., hypoxia). This information can subsequently be used to determine the signaling network dynamics that are fundamental to a given biological observation. Additionally, the use of genome-specific, rather than reference genome search databases for determining the proteins and phosphorylation sites present in a given sample, allows the accurate monitoring of the protein dynamics of specific mutations present in sample (Alfaro *et al.*, 2014; Nesvizhskii, 2014). Being able to quantitatively assess the information layer which exists between the genotype and phenotype has a distinct advantage, especially when considering that all small-molecule inhibitors and antibody-based therapeutics used in the clinic today actually target proteins rather than genes.

As was described above, these protein data need to be accurately modeled in order to establish potential signaling network models, but the near unbiased nature of MS experiments allows this to be done in a data-driven way with minimal *a priori* knowledge. Nevertheless, MS data only provides a 'snapshot' of the cellular proteome at the time of the experiment, so experiments need to be designed appropriately to accurately assess the signaling networks fundamental to a particular biological effect.

In order to more directly characterize the role of key proteins in a given cellular phenotype, the use of genome-scale RNA interference (RNAi) libraries in combination with HCS has been demonstrated in several species (Echeverri and Perrimon, 2006; Mohr *et al.*, 2010; Mohr and Perrimon, 2012; Moffat and Sabatini, 2006). By perturbing the expression of a specific protein, and measuring an appropriate phenotypic readout (e.g., proliferation or cell migration), it is possible to globally assess and elucidate proteins which seem fundamental for a given biological state. This approach has been very powerful not only at the discovery phase of investigating potential therapeutic targets, but also at the stage of validating proteins determined by, for example, MS or NGS to be involved in a given disease phenotype (Dorsett and Tuschl, 2004; Wilson *et al.*, 2013). One of the strengths that is fundamental to the success of RNAi-based screening is the fact that they can be used as a highly specific substitute for often unavailable inhibitors. A caveat being that the link between RNAi and inhibitors is not always linear however, and requires careful validation (Weiss *et al.*, 2007). Nevertheless, by systematically knocking down genes in, for example, a kinome-wide or genome-wide fashion, a global assessment of the model system can be undertaken. Additionally, this can be done in a combinatory fashion, where multiple targets can be knocked down simultaneously to monitor synthetically lethal effects where a phenotypic readout is only obtained by the simultaneous knockdown of two or more genes (Azorsa *et al.*, 2009; Kaelin, 2005; Luo *et al.*, 2009; Vizeacoumar *et al.*, 2013). Besides providing a more direct readout of the role of a particular protein in a given disease phenotype, it may also highlight proteins that were not detected by MS or genes that do not harbor a mutation, providing a complementary approach.

Computational Modeling – Understanding the Integrative Nature of Biological Networks

In order to develop a more global understanding of intra- and intercellular dynamics and adaptation it is essential to generate and combine diverse datasets describing the genetic and proteomic changes that occur during cell phenotypic changes. This in turn, requires the community to develop computational tools for real-time high-throughput live/*in situ* cell tracking. In combination with different perturbations (drugs, RNAi, CRISPR, etc.) it should be the aim of such studies to systematically interrogate the integrative nature of molecular networks, while aiming to also validate the ability of the derived computational models to predict biological systems characteristics. Given the nonlinear and integrative nature of biological systems (e.g., cancer cells or metastatic tumors) it is vital to perform computational analysis in a manner that

accepts, and in fact utilizes, this intrinsic nonlinearity of the system. There are a number of major challenges associated with processing and integrating genome-scale data, besides these intrinsic nonlinearities. First, system-wide data will invariably be of high-dimensional nature and possess measurement uncertainties, which need to be carefully accounted for in any systematic computational framework. This also entails a principled way of handling the lack of complete overlap between the different datasets to prevent skewing of the results due to missing values. Furthermore, high-throughput screening (such as HCS) typically generates very large, high-dimensional data cubes, which require a wide dynamic range in computational capacity, in particular in terms of physical memory. Thirdly, different datasets may be of very different nature both in terms of their biological meaning and mathematical representation (e.g., categorical vs. continuous data, single data-vector vs. ensemble of data-vectors).

Many different approaches for complex data modeling have been developed over the years, each with a unique, specific goal in mind (Kim *et al.*, 2011; Kreeger and Lauffenburger, 2010; Morris *et al.*, 2010; Pritchard *et al.*, 2013; Saez-Rodriguez *et al.*, 2009). Which approach is most suitable depends on the type of data and the precise biological question of interest. The Lauffenburger spectrum (Figure 4; Ideker and Lauffenburger, 2003) provides a useful starting point decide on an appropriate computational approach. In one end of this spectrum, one finds a number of high-level models for exploratory type of data analysis. This entails various popular unsupervised techniques, such as principal component analysis, factor analysis and other latent variable models (Akavia *et al.*, 2010; Hofree *et al.*, 2013; Krishnaswamy *et al.*, 2014), all of which provide means to elucidate effective low-dimensional representations of data and/or interrelationships between model components, such as to uncover potential 'drivers' of cancer (Akavia *et al.*, 2010).

In a slightly more supervised setting, one may wish to regress a number of dependent variables (e.g., proliferation, metastasis, or other phenotypic read-outs) on a selected set of independent ones (e.g., selected set of proteins or signaling pathways). Identifying relevant regressors can be done in the framework of partial least square regression for linear models (Janes *et al.*, 2005), or in nonlinear generalizations by neural networks or kernel methodologies (for instance support vector machines or gaussian processes (Bishop, 2006)). Inspired by statistical physics models, prominent methodologies within the field of deep learning have recently given rise to generative models that can handle high-dimensional and highly nonlinear correlated data in a very effective and versatile manner (Bengio, 2009; Kiros *et al.*, 2014). We envisage that these methods will find widespread use in this end of the 'Lauffenburger' spectrum in coming years (e.g., Verbist *et al.*, 2015).

Whilst these aforementioned computational techniques are useful for data mining and regression, they are not particularly geared to elucidate the 'molecular' basis let alone the causal origin for these correlations. Bayesian networks partially address this problem by identifying and modeling the conditional dependencies between observed protein expression levels, PTM patterns, etc., represented as directed edges from the independent ('parent node') to the dependent variable ('child node') (Friedman *et al.*, 2000; Husmeier, 2003; Oates and Mukherjee, 2012; Pe'er and Hachohen, 2011; Sachs *et al.*, 2005;

Figure 4 The 'Lauffenburger spectrum.' At the highest level of abstraction statistical data mining methods aim at correlate dependent with independent variables, find low-dimensional data representations and/or elucidate potential interrelationships between model components. At a somewhat lower level, Bayesian network models expand on these relationship by providing conditional dependencies of 'child' nodes on their 'parents' in a probabilistic sense. In Boolean models these conditional probabilities are replaced by logical rules. Low levels methods aim at replace these simplified rules with some that are amenable to a mechanistic interpretation. These rules may be expressed either in terms of transition probabilities (e.g., Markov chains or dynamic Bayesian networks) or kinetic reaction rates (e.g., ordinary or partial differential equations).

Zhang and Song, 2013). Markov networks provide an alternative approach, where edges are undirected and merely represent statistical couplings or 'interactions' between corresponding nodes (Wei and Li, 2007). In both cases, these edge relations are typically taken to be on a particular parametric form (e.g., logistic, gaussian, or polynomial), although recent statistical advances suggest that nonparametric approaches can be made both viable and very powerful, given sufficient data (Krishnaswamy *et al.*, 2014; Zhang and Song, 2013). Boolean networks, on the other hand, represent a particular simplification, whereby the edge relations are defined as binary functions, corresponding to logical operations (Morris *et al.*, 2010; Saez-Rodriguez *et al.*, 2009).

We emphasize that in all cases these network models are more informative than networks defined by simply forming edges between variables whenever the corresponding pairwise correlations for some data exceed some predefined value (e.g., Krishnaswamy *et al.*, 2014). These approaches do not distinguish between correlations arising from direct couplings and those that are mediated by other nodes. As such they provide only limited predictive power and are mostly useful for exploratory analysis only. In contrast, the edges in Bayesian, Markovian, or Boolean networks typically have the interpretation that neighboring nodes influence each other (directly or indirectly through hidden variables) via actual biochemical or biophysical mechanisms. In this sense, these network models are ultimately linked to models in the low-level end the 'Lauffenburger spectrum,' in terms of aiming to identify and encode 'causal' relationships.

The notion of a causal relationship is fundamentally distinct from a correlational one, as expounded and formalized in several fields (Imbens and Angrist, 1994; Pearl, 2009;

Rosenbaum and Rubin, 1983). However, causal network inference in a biological context has so far primarily been used to model regulatory networks and is generally considered an extremely challenging task (Freedman and Humphreys, 1999; Pearl, 2009). Some statistical and machine learning approaches (Friedman *et al.*, 2000; Husmeier, 2003; Sachs *et al.*, 2005) can in principle learn causal structure, but their success can only be guaranteed under very strong assumptions (Pearl, 2009; Spirtes *et al.*, 2000) that are almost certainly violated in biological settings. This is due to a range of factors including, the infeasibility of carrying out all possible interventions on the system and fundamental limitations of the data (Oates and Mukherjee, 2012).

Causal mechanistic models define the other low-level end of the 'Lauffenburger spectrum,' where time plays an explicit role. Here, the network structure is most often imposed from prior knowledge, although methodologies akin to dynamical Bayesian network may allow this to be inferred from data (Husmeier, 2003; Molinelli *et al.*, 2013). The aim of mechanistic models is to infer dynamic responses for various specific perturbations and/or estimate the underlying kinetic parameters with a clear mechanistic interpretation. These methods entail both stochastic (e.g., Markov chains) and deterministic approaches (e.g., ordinary or partial differential equations (Hoffmann *et al.*, 2002; Wilkinson, 2009)).

A recurrent theme across the whole Lauffenburger spectrum is to make a critical assessment and validation of the derived models. To compare and select models on a statistical ground involve assessment of the biases, missing values and uncertainties of the data, as well as the structure and complexity of the model and proper use of prior knowledge. We firmly

believe that these generic considerations in general should be addressed within the principled framework of Bayesian methodologies, irrespective of the particular nature of the data and corresponding models. Due to the complexity involved in cell signaling, and in pathogenesis particularly, comprehensively characterization of molecular processes requires the tight integration of experimental and computational approaches, which invariably implies the need to base the inferred biological relations on a rigorous statistical framework. Genome-scale experiments (e.g., MS, NGS, and RNAi screening) focusing on key biological questions need to be conducted, in order to subsequently integrate the knowledge gained from these different platforms using appropriate computational approaches similar to those previously mentioned. In this manner, several benefits can be obtained: (1) missing information in one dataset can be complemented by that from another, (2) the different data types can act as validation sets for one another, and (3) a comprehensive overview of how genomic information is propagated through the proteome to elicit a specific phenotype can be obtained. For example, a hit originating from an RNAi screen is more likely to be a successful clinical target if MS evidence also suggests the protein level (or phosphorylation dynamics) to be increased or if NGS has revealed there to be a mutation hitting the gene. In the case of point (1), if, for example, a given protein has not been observed by MS to be dysregulated in the diseased state, but the RNAi screen does confidently highlight the knockdown to result in a phenotype, it is likely to be an interesting candidate. Therefore, it is not only the genes and proteins which have been determined by all of the experimental methods to be of therapeutic interest, it is also the complementary nature of the technological platforms which allows for a more comprehensive interrogation of the biological model system.

In conclusion, we advocate the in-depth characterization of biological samples from several technological angles and molecular/biological perspectives, in order to accurately establish genotype-to-phenotype relationships. Ideally, where possible, this should be conducted across several time-points and under different biological conditions, to interrogate the biological system as comprehensively as possible, as certain phenotypes or protein dynamics may only be revealed under highly specific biological conditions. Importantly, by taking a global, unbiased approach to interrogate a biological system, one allows the data to highlight which proteins and/or mutations are potentially fundamental to a specific disease phenotype. This requires the implementation of careful experimental design (tailored to the specific biological question of interest), strict standard operating procedures (SOPs) for stable and reproducible sample preparation conditions and continuous quality control to ensure data is generated consistently over the generally extensive period of time it takes to collect the data. In line with the above-mentioned role of tumor subpopulations and the microenvironment, ideally this would be done in a cell-type-specific manner (e.g., tumor cells, CAFs, cancer stem cells, and other subpopulations), as this will partially deconvolute the complex interplay of the different cell types, and potentially allow for time-staggered, cell-type-specific combination therapies to be developed, thereby positively contributing to the 'war on cancer.'

Concluding Remarks

In this article, we have shown some early results of targeting cancer biology using an integrative network biology approach. By analyzing different cellular aspects using various technological platforms (e.g., MS, NGS, and HCS), a more in-depth view of cellular signaling can be obtained. This knowledge can subsequently be used for driving functional validation studies. We have highlighted some conceptual and technological advancements which facilitate this process, ranging from how mutations should be interpreted functionally, through generating and modeling phospho-proteomic data, to integrating NGS and MS data to study the propagation of mutations at the protein level. We predict that over the next years, MS and NGS technologies will become more prevalent in the clinic, as they have great potential in guiding therapeutic strategies in patients based on their tumors' protein-signaling network states and genotypic profiles. Before this becomes feasible however, the large costs associated with these types of global screens will need to be significantly reduced. Additionally, while NGS allows the interrogation of the complete genome, MS still needs to be improved in term of sensitivity. Nevertheless, advancements in this field are consistently on-going, resulting in greater coverage of cellular (phospho-) proteomes, and we are likely to see this pattern continue (Zhou *et al.*, 2013; Sharma *et al.*, 2014; Branca *et al.*, 2014). With greater coverage and improved sensitivity of the technologies described, creating more accurate molecular maps of cellular processes will become a reality and feed into novel target detection efforts.

Development of a Global, Predictive Biological Model of Cell Behavior

A key target for the (Cancer) network biologists is to integrate global quantitative datasets in order to model core signaling networks that drive the phenotypic changes occurring during the many responses of cancer cells. In our own lab we employ nonlinear Bayesian and deep learning approaches for this task, such that the information flow can be represented in terms of a probabilistic model of the network state, as a function of time. In turn, this can facilitate the generation of quantitative predictions of the time-dependent changes in cell phenotypes, based on the state of regulatory nodes in the signaling networks. We hypothesize that this aim is of strategic importance for future clinical applications as well as in basic biology, where a major bottleneck is our inability to predict cell behavior. Finally, we argue that such data-driven, nonlinear forecasting models as described above will eventually identify multi-node perturbations correlated to phenotypic transitions and events during cancer progression and tumor evolution. It should therefore be a concerted goal of the entire network biology community to identify regulatory networks controlling these processes and to predict key nodes for novel targeted therapies. Efforts to this end will hold great potential for identifying network-based therapeutic strategies and to target multiple key nodes, preventing cancer cell migration and allowing biologists to alter invasive phenotypes. This type of approach holds great promise for lowering the global cancer burden and that of many, if not all, other complex diseases and drug resistance cases.

Genomics for Old and New Questions

Among the long-standing aims of biology, understanding how organisms function, develop, and adapt occupies a central position in the field. In modern biology, researchers pursue some of the same standard questions, but with a remarkable advancement: they are now able to connect intricate biological processes to the most fundamental source of biological information – the genome. As it has been known for decades, the genome of a species contains the instructions required for its evolutionary perpetuation, including the development, functioning and reproduction of the organism carrying it. The 20th century has witnessed a step-wise advancement in our comprehension of the genome structure and function; from the role of DNA in hereditary, passing through its biochemical structure, genetic coding logic, and regulatory mechanisms. The launch of the Human Genome Project in the 1990s gave the start to several genome consortiums aiming to

sequence model organisms’ genomes (e.g., yeast, fruit fly, mouse; see [Table 1](#)). In a simplified overview, a genome project includes sequencing the nucleotides of short fragments of DNA, covering the whole organism genome; followed by the computational assembly of these short segments into large sequences representing the chromosomes. Finally, the genome annotation step identifies different functional elements in the assembled sequence (such as protein-coding regions and regulatory motifs). In recent years, there has been an explosion in the number of genomic studies published, encouraged by the advance in the sequencing technologies (the so-called ‘next-generation sequencing’) and bioinformatic analysis tools. The massively parallel sequencing implemented nowadays rapidly generates high amounts of genome-wide data, and allows genomics to shift to pursue biological questions in a unprecedented way, connecting variation at the genome level to its functional consequences ([Koboldt et al., 2013](#)).

Table 1 Some landmark genome projects that have contributed to the understanding of genome structure, function, and evolution

Organism	Importance	References
<i>Haemophilus influenza</i> (bacterium)	First complete prokaryotic genome	Fleischmann et al. (1995)
<i>Saccharomyces cerevisiae</i> (yeast)	First complete eukaryotic genome	Goffeau et al. (1996)

12 <i>Drosophila</i> genomes	Comparative analysis of fly species	Drosophila 12 Genomes Consortium (2007)
1000 human genomes	Characterization of human genetic variation across populations	Durbin et al. (2010)

The simple description given above may create the deceptive impression that the link between nucleotide sequences in the genome and their function is direct and unambiguous. However, the genetic information encoded in the DNA may not be evident when a single genome is read. To put in another way, when we try to understand what portions of the genomes are functionally relevant and how the intricate biological processes arise from them, to use a well-known metaphor, the 'book of life' resembles more an encrypted file.

In order to identify functionally relevant elements, comparison of genome sequences from different species provides a powerful strategy. The justification behind such comparative framework is that portions of the genome that encode for biologically important functions tend to be more conserved across different species than nonfunctional regions (Hardison, 2003). The rationale is simple: genomes are continually evolving; therefore, if sequences from different species remain with high similarity, despite their independent evolutionary trajectories since the last common ancestor, it is reasonable to assume that they were spared by evolution because they play a functional role, which is usually subject to purifying selection, whereas nonfunctional portions are free to accumulate mutations, or even be deleted from the genome. This approach can be used to identify genes, and it is particularly useful for finding regulatory regions, whose structure is more heterogeneous than that of protein-coding sequences. Therefore, when researchers find conserved sequences from evolutionary distant species (such as human, mouse, and fly), they conclude this sequence is a good candidate for a functional element, because it retained similar information even in species that have been diverging for millions of years. It must be noted, on the other hand, that this conservative approach may fail to identify genes that underwent intense divergence in a short evolutionary period, such as that driven by rapid positive selection, for example. Thus, complementary annotation approaches, such as measurements of protein-coding potential, will probably improve genome analyses (Zhang *et al.*, 2012).

In this context, it is not surprising that the human genome sequencing was followed by similar projects in other model organisms (Table 1 shows that several pioneer genome projects were published in a short period of time). Even if one is interested in exploring genome function of a single species (e.g., identifying genes contributing to human diseases), evolutionary comparisons with genomes from diverse taxa are imperative (Collins *et al.*, 2003). Nevertheless, identifying functional elements in the genome is just the first step for investigating how genes work, interact and evolve. Detailed functional experiments are required to confirm and determine the specific biological functions of genetic elements (Miklos and Rubin, 1996).

Besides the role of identifying functional elements in genomic studies, comparative genomics is also a powerful strategy to investigate evolutionary questions (Hardison, 2003). Comparison of genomes in a phylogenetic framework, ranging from closely related species to taxa in different kingdoms, for example, may help to elucidate exciting questions: What is the basic set of genes common to diverse taxa? How often new genes are created? What are the evolutionary processes involved in diversification and adaptation? An illustrative scheme is provided in Figure 1. In the other extreme,

comparison of genomes from individuals of the same species can also be applied to pinpoint specific genetic variations underlying relevant phenotypes (such as adaptive traits or even diseases factors) in genome-wide association studies.

A complementary set of questions we are now able to investigate relates to the origin of genetic novelties. In the past decades, many studies have explored the creation of new genetic elements, how they integrated in genetic systems, and their roles in phenotypic evolution (reviewed in Long *et al.*, 2013).

Case Studies: New Genes for Old and New Functions

In the rest of this article, we will focus on studies that took advantage of genomic data to identify new genes and then investigate fundamental questions about their evolution, especially those related to cell biology functions. We refer to new genes as distinct loci that originated at a certain time in the evolutionary history of a species and that were not present in the ancestors (Chen *et al.*, 2013). New genes offer a particularly convenient study model to address evolutionary questions because, given their relatively recent origin, they still carry the evolutionary signatures that shaped their formation and molecular evolution (Long *et al.*, 2013). Furthermore, due to the great advance of computational and molecular biology techniques, we can now explore some evolutionary problems in a precise and mechanistic way, identifying patterns, elaborating hypotheses, and testing their predictions, in order to achieve a comprehensive view of new genes evolution, connecting genetic and functional divergence.

New genes can originate from diverse mechanisms, such as DNA duplication, retrotransposition (RNA-based duplication), gene fission or fusion, and *de novo* creation (Chen *et al.*, 2013). These new loci can be identified through syntenic alignments of genomes from different species. Genes present in some (or even a single) species but absent in all outgroup species are good candidates for having a recent origination (see Figure 1). Furthermore, structural features in the gene and flanking regions can be used to infer the mechanisms of its formation. After identifying a new gene candidate, studies typically seek to confirm its functionality (analyzing its open reading frame length and transcription products, for instance) and explore signatures of molecular evolution (such as synonymous/non-synonymous substitutions rates). Ideally, the ultimate goal is to connect the evolution at the nucleotide sequence to its phenotypic impact, evaluating the functional and adaptive impact of the new gene origination.

Basic cellular functions have been considered to be encoded by a set of old, conserved genes, since some essential processes and pathways are found in evolutionary distant organisms (Miklos and Rubin, 1996), whereas new genes would be involved in minor, dispensable activities. Nevertheless, an increasing number of studies have been reporting the contribution of new genes to basic cellular processes. They show that new genes can be integrated into conserved pathways, and even become essential for viability and reproduction (Chen *et al.*, 2010). Next, we will explore how the study of new genes can be connected to cellular biology. We will focus on examples of gene movement between chromosomes and the

Figure 1 Schematic representation of different questions addressed in a comparative genomics approach (based on Hardison, 2003). At left, colored boxes represent genes present in different animal groups in the phylogeny (cnidarian, fly, fish, mouse, and human); at right, a phylogeny of closely related fly species illustrating a syntenic alignment used to find a new gene (pink box).

integration of new genes into basic cellular functions (namely, gene regulatory networks, cell division, and protein traffic) to argue that the evolution of new genes can shed light on fundamental cellular mechanisms. With that, we hope to stimulate future insightful connections between the genomics and cell biology fields.

Gene Traffic

Cytogenetics played a central role in the early decades of genetic studies. Enough is to mention, for instance, that Thomas Morgan and his students were pioneers in connecting chromosome structure to heredity; and Theodosius Dobzhansky and his students were able to use structural variations (such as chromosomal inversions) as molecular markers for studying variation in natural populations of *Drosophila*, all with elementary microscopy techniques. With the recent advancement of molecular biology techniques, however, evolutionary studies have changed its focus from variation of structure to the specific changes on nucleotide sequences. In this context, genomic analyses allow the investigation of biological questions at a finer scale. However, basic structural data can be surprisingly informative for testing evolutionary hypotheses in a comparative genomics framework. We will illustrate this point using recent findings of new genes

movement patterns in mammals (e.g., humans and rodents) and insects (e.g., flies, mosquitoes, and silkworms).

Several studies demonstrated that the distribution of retrogenes (new loci created through RNA-based duplication) and their parental copies in the genomes are not random with respect to their chromosomal position; instead, new genes movement follows a preferential direction (gene traffic). Analyses focusing on the *Drosophila melanogaster* genome (Betran *et al.*, 2002) and more recent comparative investigations using genomes from 12 *Drosophila* species (Meisel *et al.*, 2009; Vıbranovski *et al.*, 2009b), for example, revealed that retrogenes derived from X-linked genes preferentially move to autosomes ($X \rightarrow A$), contrasting to random expectations. More interestingly, the large majority of these $X \rightarrow A$ retrogenes are expressed in testis, suggesting a connection between male-biased function and chromosomal location. To some extent, a similar pattern is observed in human and mouse genomes (Emerson *et al.*, 2004), in which there is an excess of $X \rightarrow A$ movement of retrogenes, as well as male expression bias. However, in these mammal genomes there is also a significant excess of retrogenes moving in the opposite direction ($A \rightarrow X$), which present either female or unbiased expressions. Interestingly, a somewhat symmetrical pattern is observed in silkworms (in which females are ZW and males are ZZ), whose retrogenes tend to move out of the Z chromosome and have ovary-biased expression (Wang *et al.*, 2012). Additionally, recent comparative analyses of 16

mosquito genomes also found an excess of gene translocations from the X to the autosomes in these species (Neafsey *et al.*, 2015).

How can these findings be explained in an evolutionary perspective? Gene traffic patterns are probably explained by both adaptive and mechanistic forces acting on the origination and insertion of new genes. Several models have been proposed to explain the specific roles of each force, and their relative importance is still debated (summarized in Long *et al.*, 2012). Among the plausible models for explaining why new genes have a preferential movement across the genome, we find the sexual antagonism hypothesis, which predicts that dominant beneficial mutations to females but detrimental to males have higher probability of fixation by natural selection on the X chromosome, while recessive ones have higher probability of fixation on the autosomes. Conversely, dominant and recessive mutations that are beneficial to males but detrimental to females have higher probability of fixation on the autosomes and on the X chromosome, respectively (Rice, 1984; Charlesworth *et al.*, 1987). Other, more mechanistic, explanations are the meiotic sex-chromosome inactivation (Vibrantovski *et al.*, 2009; Vibrantovski, 2014) and the dosage compensation models (Vicoso and Charlesworth, 2009). Both hypotheses suggest that processes occurring in the X chromosome reduce the expression of male-biased genes (such as sex-chromosome inactivation and dosage compensation) and, as a consequence, natural selection favors the relocation of these genes to autosomes. Finally, a recently proposed hypothesis (Díaz-Castillo and Ranz, 2012) suggests that the accumulation of testis-expressed retrogenes in *Drosophila* autosomes can also be explained by the nuclear dynamics of chromosome domains in the male germ line. They argue that the preferential integration of male-expressed retrogenes on autosomes is caused by the increased accessibility of open chromatin domains with testis expression during spermatogenesis, due to distinct chromosome interactions with the nuclear lamin. The lower fraction of accessible domains on the X chromosome in the male germ line would also explain the paucity of retrogenes in this chromosome. This model illustrates how data regarding gene locations can be combined with structural information to provide new explanatory hypotheses.

There is still intense debate regarding the limitations and explanatory power of each model. The general patterns of retrogene movement are probably caused by a combination of factors, each one promoted by a different model. Further understanding will certainly emerge from the collection of more genomic, expression and functional data. In any case, these findings show how basic structural information (in this case, chromosomal distribution of new genes) can be connected to genomic data to reveal compelling patterns. We believe that future investigations connecting gene distribution to other chromosome structures (such as chromatin states and chromosomal domains) may provide exciting evolutionary insights.

Gene Regulatory Networks

A key process for proper cellular function is gene regulation. Spatial and temporal transcriptional activation of genes is

determined by complex and extensive regulatory networks, often involving signaling cascades, protein complexes assembly and transcription factors binding to gene regulatory motifs. Recent large-scale genomic analyses have described general patterns regarding the intricate regulatory networks from some model organisms (Mackay, 2014), which allows us to understand the number of functional elements, connectivity and logic of networks topologies. However, little is known about how regulatory networks actually evolve at a high resolution, how they can be rewired and expanded, and how their constituent elements adapt in concert. A good way to explore that is by investigating how the addition of new elements impact preexisting networks. Next, we will illustrate how the recent integration of gene duplicates provides insights about network evolution.

In one example, the gene *Zeus* (*Drcd-1r*) originated through retrotransposition from a X-linked parental gene, *Caf40* (*Drcd-1*), in the ancestor of *D. melanogaster*, *D. simulans*, *D. mauritiana* and *D. sechellia*, around 4–6 million years ago (Quezada-Díaz *et al.*, 2010). *Caf40* encodes a highly evolutionary conserved DNA-binding protein and takes part in a transcription regulatory complex. Interestingly, *Zeus* protein sequence (with around 300 residues) underwent intense divergence from its parent, accumulating more than 150 amino-acid substitutions in a short evolutionary period, with evidence of positive natural selection, whereas the parental copy accumulated less than ten amino-acid substitutions in the same species (Chen *et al.*, 2012). Also, *Zeus* regulation also diverged, acquiring restricted testis-expression, and being subject to histone modifications (Arthur *et al.*, 2014), while the parental *Caf40* remained ubiquitously expressed. Using chromatin immunoprecipitation followed by microarray assays (ChIP-chip), Chen *et al.* (2012) demonstrated that *Zeus* protein binding sites across the genome have diverged to large extent from the parental gene, promoting the upregulation of male-biased genes and downregulation of female-biased genes. Furthermore, *Zeus* knockout shows a dramatic negative effect on male fertility, evidencing the functional relevance of *Zeus* integration into the regulatory network.

A similar pattern was investigated with another regulator recently duplicated in the *D. melanogaster* species complex. *Nsr* (novel spermatogenesis regulator) originated through DNA duplication from the *kep1* locus in the same phylogenetic branch of *Zeus*, and also exhibits evidence of positive selection. The parental gene encodes a conserved RNA-binding regulator, with ubiquitous expression, whereas *nsr* expression is restricted to testis. Alike the previous example, *nsr* knockout also decreases male fertility. Detailed electron microscope revealed that *nsr* knockout results in loss of the outer dynein arms of the sperm axoneme, generating abnormal sperm structures (Ding *et al.*, 2010). More interesting, the authors suggest that *Nsr* functional divergence may be related to its subcellular localization, which is much broader than that of *Kep1* protein. Therefore, according to their hypothesis, *nsr* acquired new male reproductive function through the regulation of mRNA of preexisting genes required for spermatogenesis. Curiously, the sperm maturation processes affected here are very conserved during evolution.

Both examples mentioned above exemplify how new genes can be integrated into preexisting regulatory networks and

acquire important functions. In this process, the new gene can substantially diverge from the parental locus, changing its interaction partners, expression pattern and subcellular localization. This integration can impact the overall network architecture, and promote its rewiring, which can explain, for example, why some new genes quickly acquired crucial functions in *Drosophila* and even became essential for development and other conserved processes, despite their recent origin (Chen *et al.*, 2010; Kemkemer and Long, 2014).

Cell Division

Another cellular process that, despite being highly fundamental and evolutionary conserved, may also be impacted by new gene recruitment is cell division. The intricate cellular mechanisms driving the accurate distribution of the duplicated genome during cell division are essential to ensure proper cellular viability and development. Chromosome alignment and segregation require the interaction between kinetochore proteins associated with the centromere and the spindle microtubules, usually involving conserved protein complexes (Cheeseman and Desai, 2008).

In a detailed investigation, Ross *et al.* (2013) showed that the new duplicate gene *Umbrea*, originated through DNA duplication 12–15 million years ago in *Drosophila*, evolved an essential role for chromosome dynamics during mitotic division. Comparing sequences from a range of species and manipulating their protein structure, they were able to reconstruct the step-wise trajectory of *Umbrea* evolution. After duplication from the parental *HP1B* (which encodes a heterochromatin protein involved in gene regulation), *Umbrea* divergence involved the loss of an ancestral heterochromatin-localizing domain, and other changes that rewired its protein interaction network and led to centromere localization. Surprisingly, whereas the parental *HP1B* gene is dispensable for viability, *Umbrea* developed an essential function, as demonstrated by the high proportion of mitotic errors found in knockdown cells (Ross *et al.*, 2013; Chen *et al.*, 2010).

The authors propose that recurrent changes at centromeric regions may explain the recruitment of new duplicate genes coding for centromeric proteins. *Umbrea* constitutes a notable example of how new genes can be integrated into preexisting cellular networks and impact its overall architecture, even for fundamental cellular processes, such as chromosome segregation.

Protein Traffic

As a final example, we will discuss a case study that challenges our concepts of conservation and homology of subcellular components. Many complex cellular structures, such as organelles, are found in phylogenetic distant groups of organisms. The parsimonious interpretation is that those shared features are homologous, that is, they are ancient structures inherited from a common ancestor. There at least some cases, however, in which the finding of complex structures found in distant organisms are better explained by independent convergent evolution, rather than by shared inheritance.

The hypothesis of independent origins was explored with specialized secretory vesicles called dense core granules (DCGs). These vesicles accumulate in the cytoplasm and function as storage reservoirs, until extracellular signals cause their fusion with the plasma membrane and the extracellular release of their content (reviewed in Elde *et al.*, 2007). Because DCGs are found in a wide range of eukaryotes (e.g., mammals, fungi, and protozoans), the prevailing hypothesis was that they were already present in the early eukaryotic ancestor. However, analyses of the molecular composition of DCGs in mammals and ciliates (groups that diverged more than 1 billion years ago) failed to find homolog proteins, and some molecular mechanisms involved in DCGs processes are fundamentally different in these groups. Such observations support the idea that these secretory granules had independent origins in distinct phylogenetic lineages.

A supplementary example comes from clathrin proteins involved in endocytosis. This process is highly conserved in eukaryotes, and there is strong evidence for the shared inheritance of the underlying genes. Nevertheless, recent duplications of clathrin genes during chordate evolution generated distinct isoforms with tissue-specific functions (Elde *et al.*, 2007). This instance illustrates how the inheritance of ancient genes, combined with lineage-specific duplications, can lead to functional divergence and adaptation. The possibility that other common cellular features are the result of convergent processes, rather than representing shared inheritance, provides an exciting alternative view of the evolutionary history of complex structures.

Perspectives

The recruitment of new genes to play a role in fundamental cellular processes may be a general and recurrent theme in evolution, rather than represent exceptional events. Table 2 summarizes several new genes documented in *Drosophila* with basic cellular functions. Note that these genes originated in diverse phylogenetic branches in the *Drosophila* history, ranging from 0 to 25 million years ago (for the sake of comparison, this upper limit corresponds to the time that separates humans from our primate cousins *Rhesus*, a relatively recent event in evolutionary terms). In the near future, the collection of additional complete genomes will improve our ability to discover and date the origin of genes more precisely. Allied to experimental molecular biology techniques, this knowledge will allow a more mechanistic understanding of the functional evolution of new genes, and of biological functions in general. We believe that future cases of novel genes implicated in basic cellular processes will underscore their relevance for adaptation.

The evolutionary relevance of new genetic elements also points to the appealing perspective of their significance in shaping human-specific traits, as well as contributing to diseases. Despite variable estimates, we can conservatively conclude that at least 300 genes are specific of the human lineage, and other 1000 are only found in primates (Zhang and Long, 2014). Strikingly, transcriptome analyses revealed that a larger proportion of new genes are expressed in human brains during development when compared to mouse, and also suggested

Table 2 Examples of new genes involved in basic cellular processes in *Drosophila* species

Gene name	Gene age (million years)	Cellular process
Jingwei	0–3	Alcohol metabolism
p24-related-2	0–3	Golgi vesicle transport
Cyp9f2	3–6	Intracellular oxidoreductase activity
Xcbp1	3–6	Chaperone
TfIIA-S-2	6–11	Transcription factor
Ribosomal protein S28a	6–11	Ribosomal structural constituent
Methuselah-like 6	6–11	Membrane G-protein coupled receptor
ACXA	11–25	Intracellular signal transduction
Chemosensory protein B 93b	11–25	Detection of pheromones
Scavenger receptor class C, type III	11–25	Cellular internalization of foreign material
Lysozyme X	11–25	Lysozyme activity, defense against bacteria
Ribosomal protein L37b	11–25	Ribosomal structural constituent

that these genes originated in the same evolutionary period during which human neocortex was expanding (Zhang *et al.*, 2011). Such findings demonstrate how genome-wide expression comparisons can be used to shed light on long-standing questions regarding human traits. Additionally, detailed experimental investigations have shown the implication of young genes in diseases. Some remarkable examples include genes related to tumors, such as the hominoid-specific *TBC1D3* (Wainszelbaum *et al.*, 2008), which is involved in cellular signaling and trafficking; and the primate-specific *CT45A1*, which upregulates oncogenic and metastatic genes (Shang *et al.*, 2014). Moreover, these examples illustrate how evolutionary and cellular approaches can be combined to explore relevant questions.

The finding that distant related taxa shares many common cellular processes, and even ancient genes, may give the false impression that basic functions, and the genes underlying them, are not affected by evolution, and remain unaltered at the molecular level. This view is not in accordance with our modern view of evolution. The existence of deeply conserved processes does not imply that their underlying components have been static over evolutionary time. Cellular processes are highly dynamic, and so is their evolution. During their evolutionary history, organisms face diverse challenges, such as changing environments, competition, and pathogenic attacks. Therefore, it is not unexpected that the genetic elements interacting in a network evolve over time, improving and renewing the overall system. Furthermore, even when a certain process is conserved across long evolutionary periods (such as the cell division mechanisms mentioned above), the molecular components that produce it may undergo a dynamic turnover. With these examples, our aim is to argue for the idea that, far from providing just anecdotal reports, the evolution of new gene functions can help to illuminate main

evolutionary mechanisms and understand biological processes and structures.

Glossary

Competing endogenous ribonucleic acid (ceRNA) A form of RNAs molecules that regulate other RNA transcripts by competing for shared microRNAs.

Complementary deoxyribonucleic acid (cDNA) A form of DNA synthesized from a messenger RNA template in a reaction catalyzed by the enzyme reverse transcriptase.

Expressed sequence tags (ESTs) A short subsequence of a cDNA sequence.

Fluorescent *in situ* RNA sequencing (FISSEQ) A method of sequencing DNA by the use of colonies and cycles of fluorescent deoxyribonucleotide triphosphate (dNTP) incorporation.

Long noncoding RNA (lncRNA) Nonprotein coding transcripts longer than 200 nucleotides.

Messenger RNA (mRNA) A class of RNA molecules functions as the template for protein synthesis.

MicroRNA (miRNA) A class of naturally occurring, small noncoding RNA molecules which functions in RNA silencing and posttranscriptional regulation of gene expression.

Noncoding RNA (ncRNA) A class of RNA molecules which is not translated into a protein.

Piwi-interacting RNA (piRNA) A class of small noncoding RNAs that interacts with piwi-domain-containing proteins.

RNA sequencing (RNA-seq) A technique which is used to map the transcribed.

Sequencing by oligonucleotide ligation and detection (SOLiD) A next-generation sequencing platform.

Serial analysis of gene expression (SAGE) A technique to produce a snapshot of the messenger RNA in the form of small tags that correspond to fragments of those transcripts.

Single-molecule real-time sequencing (SMRT) A parallelised single molecule DNA sequencing by synthesis technology.

Small nuclear RNA (snRNA) A class of small RNA molecules confined to the nucleus.

Small nucleolar RNA (snoRNA) A class of small RNAs molecules which is associated with the eukaryotic nucleus components of small nucleolar ribonucleoproteins.

snoRNA-derived RNA (sdRNA) A small noncoding RNA of uniform length and with distinct sequences that are ubiquitously detected across eukaryotes.

Introduction

Transcriptomics is the study of the ‘transcriptome,’ a term whose first use, to signify an entire set of transcripts, has been attributed to Charles Auffray (Pietu *et al.*, 1999). The term transcriptome is now widely understood to mean the complete set of all the ribonucleic acid (RNA) molecules expressed in some given entity, such as a cell, tissue, or organism (Morozova *et al.*, 2009; Wolf, 2013).

Transcriptomics encompasses everything relating to RNAs. This includes their transcription and expression levels, functions, locations, trafficking, and degradation. It also includes the structures of transcripts and their parent genes with regard to start sites, 5′ and 3′ end sequences, splicing patterns, and posttranscriptional modifications (Wang *et al.*, 2009). Transcriptomics covers all types of transcripts, including messenger RNAs (mRNAs), microRNAs (miRNAs), and different types of long noncoding RNAs (lncRNAs).

Modern transcriptomics uses high-throughput methods to analyze the expression of multiple transcripts in different physiological or pathological conditions and this is rapidly expanding our understanding of the relationships between the transcriptome and the phenotype across a wide range of living entities.

Evolution of High-Throughput Transcriptomic Technologies

The comprehensive study of the transcriptome has not been feasible until recently because capturing full catalogs of transcripts and their variations is complicated and requires sophisticated technology. Over the years, several different kinds of high-throughput technologies have been developed to profile and quantify transcript expression. Much of the early knowledge of the transcriptome was derived from gene predictions and traditional methodologies that used complementary deoxyribonucleic acid (cDNA) clones to generate expressed sequence tags (ESTs), followed by sequencing using automated Sanger sequencing technology, as exemplified by the human genome project (Adama *et al.*, 1991). One pioneering quantitative transcriptomic study employed serial analysis of gene expression (SAGE) on 1000 tags to characterize the gene expression pattern in human pancreas (Velculescu *et al.*, 1995). In 1995, early high-capacity microarrays containing cDNA spotted onto microscope-sized glass slides were developed and applied to measure expression of 45 Arabidopsis genes in parallel (Schena *et al.*, 1995).

Recent years have seen the emergence of RNA sequencing (RNA-seq), which encompasses a variety of next-generation sequencing techniques for determining the sequence and

potentially also the levels of RNA transcripts (Chu and Corey, 2012; Nagalakshmi *et al.*, 2008; Wilhelm *et al.*, 2008; Mortazavi *et al.*, 2008). At present, sequencing technology still involves several challenges for users, including cost, availability, and the complexity and error vulnerability of sequence assembly. For these reasons, array-based technology is still widely used in transcriptome profiling. However, compared to the new sequencing approaches, which are able to deliver readings on exact transcription boundaries and unmapped transcripts without requiring predefined gene or transcript probes (Metzker, 2009; Wang *et al.*, 2009), array technology is limited by the probe-based nature of microarrays.

With the advent of RNA-seq, the possibility of sequencing the entire transcriptome has become a reality (Ozsolak and Milos, 2010; Marguerat and Bahler, 2010). Only the more abundant transcripts are usually detected by traditional approaches like EST sequencing whereas RNA-seq, when employed with adequate sequencing depth (100–1000 reads per base pair of a transcript), is capable of delivering an almost complete capture of a transcriptome (Martin and Wang, 2011). Furthermore, RNA-seq allows for a full genome-wide assessment of transcripts, with a wide dynamic range of expression levels (Nookaew *et al.*, 2012). Unlike current array technologies, it can also be used as a discovery tool to identify novel transcripts such as lncRNAs, in addition to applications in analysis of differential gene expression and alternative splicing of transcripts.

As summarized in the left panel of Figure 1, most RNA-seq approaches to date have used indirect methodologies in which

extracted mRNAs or total RNAs are first converted into a library of cDNAs containing sequencing adapters. A high-throughput DNA sequencing technology is then used to sequence the cDNA fragments from one end or both ends, rendering an output which is comprised of short sequences. The resulting short reads are preprocessed to minimize sequencing errors and then assembled into longer sequences putatively corresponding to the RNAs in the original sample. By sequencing a large number of short transcripts in parallel and piecing together the resultant short reads, it is now becoming possible to collect complete sets of transcriptome data (Metzker, 2009).

Most next-generation sequencing platforms have typically delivered quite short sequence reads (35–500 bp) (Metzker, 2009; Shendure and Ji, 2008). This then requires high-powered computing systems with large memory and many cores to run the parallel algorithms needed to reconstruct the full-length transcripts. Such sequencing platforms have relatively high error rates and raise informatics challenges, due to the short reads and sometimes biased coverage (Guo *et al.*, 2012; Wang *et al.*, 2009; Bahassi and Stambrook, 2014).

With the rapid evolution of assembly algorithms and improvements in data quality, newer RNA sequence technologies, for example single-molecule, real-time sequencing technology (SMRT) or nanopore sequencers, described further below (Mikheyev and Tin, 2014; Maitra *et al.*, 2012), are addressing the above challenges and providing longer reads up to several kilobases, which make them capable of fully sequencing a transcript in a single run.

Figure 1 Indirect and direct approaches to RNA-seq. Early high-throughput approaches to RNA-seq have utilized cDNA (left) but new alternatives such as nanopore sequencing (right) can sequence RNA directly. In one implementation of this strategy, the RNA strand binds to an enzyme or other immobilizing molecule (green) which ratchets the RNA one base at a time through a molecular nanopore channel (blue) embedded in a membrane. The nanopore conducts an electrical current across the membrane. As each RNA base passes through the nanopore it disrupts the current in a characteristic way, allowing the base to be identified.

The goal now is to extend read lengths to eliminate the need for assembly. On the SMRT platform, the average read length is approximately 3000 bp but can extend to over 20 000 bp, making it possible to sequence most RNA transcripts in a single read, although additional reads would be needed to ensure high-quality coverage and improve throughput (Martin and Wang, 2011). Many scientists now believe that continuous improvement in sequencing protocols and increases in throughput will shape the future of transcriptome sequencing to the point that no assembly will be required (Bahassi and Stambrook, 2014; Martin and Wang, 2011).

Another recent advance is to combine RNA-seq with fluorescent *in situ* hybridization to generate information simultaneously on both the levels and the cellular localization of transcripts. Termed fluorescent *in situ* RNA-seq (FISSEQ), RNA is reverse transcribed *in situ* and the cDNA copied by rolling-circle amplification to generate DNA 'nanoballs,' which are then sequenced in cells using 'sequencing by oligonucleotide ligation and detection' (SOLiD) technology. The SOLiD technique involves the sequential hybridization of fluorescently labeled two base probes, which can then be imaged to determine the sequence of the transcript contained within a nanoball. In the initial publication describing the FISSEQ technique (Lee *et al.*, 2014), the authors successfully sequenced ~12 500 nanoballs in primary human fibroblasts, with a median base error rate of only 0.64%. Although this emerging technique will require further optimization before it is adopted more widely, the ability to simultaneously generate sequence and positional information is an important breakthrough in transcriptomics research.

Most available high-throughput technologies require RNA conversion into cDNA but novel approaches such as nanopore sequencing (Ayub and Bayley, 2012) now make it possible to sequence RNA directly (Figure 1). This eliminates the need for reverse transcription and sequence assembly, two important inherent sources of error in the indirect approaches presently being used. Direct sequencing technologies currently under development entail passing the RNA one base at a time through either a solid state nanopore or a molecular nanopore positioned across an electrical field. As each different RNA base (A, C, G, or U) is fed through the pore it produces a distinctive change in the current flow across the field. However, this occurs too rapidly to detect using existing technology so the RNA is first transiently immobilized, for example by binding to some kind of capture molecule that acts as a decelerating gear to slow the passage of RNA bases through the pore, allowing current changes to be detected. Proteins such as α -hemolysin, which is able to form heptameric channels in biomembranes, have been used successfully as molecular nanopores in direct DNA sequencing and can be adapted for RNA-seq by targeted mutation, in combination with biotin-streptavidin binding or other capture strategies to immobilize the RNA strand.

One important caveat to keep in mind for all these methods is that when large numbers of measurements are made simultaneously, the number of errors is also potentially large, even when the error rate is very low. The accuracy of any high-throughput data, whether from microarrays or next-generation sequencing, should therefore always be validated by an

alternative procedure, such as polymerase chain reaction (PCR) (Milward *et al.*, 2012; Piepenburg *et al.*, 2006).

Exploring the Interactive Transcriptome

The technological advances described above are not only extending our knowledge of protein-coding mRNA molecules but are also shedding new light on some of the previously unrecognized or underappreciated noncoding components of the transcriptome and how the interactions among these components modify the transcriptomic profile under different conditions.

Ribosomal RNA and transfer RNA have been recognized since the 1950s as having biological functions other than protein coding and more recent advances in RNA technologies have led to the identification of many different classes of 'noncoding' RNAs (ncRNAs). Most ncRNAs are now believed to have important functions in regulating other RNAs and consequently in modulating the transcriptome.

For example, miRNA have long been recognized for their ability to bind to and induce degradation of target mRNA transcripts (Lee *et al.*, 1993); small nuclear RNAs (snRNAs) have critical, possibly even catalytic, roles in the splicing of mRNA transcripts (Matera and Wang, 2014; Valadkhan *et al.*, 2009); and small nucleolar RNAs (snoRNA) are also primarily associated with modification of other RNA species, including rRNA and snRNA. Furthermore, snoRNA itself is generally derived from spliced introns of transcripts, which escape the usual fate of degradation by forming protein complexes, and may undergo further processing to liberate snoRNA-derived RNA (sdRNA), an ncRNA similar to miRNA that in turn may have roles in regulating gene expression (Bratkovic and Rogeljić, 2014; Falaleeva and Stamm, 2013). In addition, recent studies have revealed that lncRNA can influence transcription by directly interacting with the transcription machinery or specific transcription factors. At the posttranscriptional level, lncRNAs can influence mRNA processing (e.g., as natural antisense transcripts) (Beltran *et al.*, 2008; Faghghi and Wahlestedt, 2009), translation control, and mRNA stability.

To get an idea of the probable scale of transcriptomic interactions, the class of mature miRNAs in humans alone contains over 2500 different members (miRBase 21), the class of human lncRNAs has over 10 000 members, and the class of Piwi-interacting RNA (piRNA), which has roles in epigenetic gene regulation through transcriptional gene silencing, is even larger, with perhaps hundreds of thousands or even millions of distinct piRNAs (Brennecke *et al.*, 2007; Siomi *et al.*, 2011; Ross *et al.*, 2014). The potential intricacy is even more apparent when it is realized that many ncRNAs show tissue- and time-specific expression (Landgraf *et al.*, 2007).

Another fascinating class of RNA molecules whose membership is being rapidly expanded through deep sequencing approaches is circular RNA, which can consist of exons only, introns only, or both. Alternative circularization, in conjunction with alternative splicing, appears capable of producing multiple circular RNAs from individual human genes at thousands of different genomic loci, suggesting that this class also contains a large number of members, again adding a

further layer to the transcriptome and its regulation (Zhang *et al.*, 2014).

In addition, over one hundred RNA modifications have now been identified, including methylation, uridylation, and other tailing motifs, providing yet another level of complexity superimposed on the various transcriptome elements described above (Lee *et al.*, 2014).

The recognition that there is a considerable degree of cross-talk between different RNA species has also led to the concept of competing endogenous RNA (ceRNA) (Salmena *et al.*, 2011), a network of RNA species that regulates one another by competing for binding to shared miRNAs. Through this competition, ceRNA populations act as a natural miRNA ‘sponge’ by titrating miRNA availability. Although still in its infancy, a number of recent discoveries provide support for this hypothesis, most notably the ceRNA network involving the tumor suppressor *PTEN* (Poliseno *et al.*, 2010). This study reports evidence for biological activity of the mRNAs of certain oncogenes such as *PTEN* and *KRAS* (independent of their protein coding functions), as well as for biological activity of the transcripts of their pseudogenes, including roles in growth suppression. The antisense transcript of the *PTEN* pseudogene likewise displays biological activity, for example in cell cycle arrest (Johnsson *et al.*, 2013).

Although the full complexity of transcriptome interactions remains to be unraveled, the examples above serve to illustrate the extensive and multifaceted nature of the interconnections and cross talk among different ncRNA species. From the perspective of transcriptomics, not only is it important to determine the different types and relative amounts of the various ncRNA species, but it is also essential to understand how they interact to regulate each other and thereby shape the transcriptome.

In addition to effects on transcription and mRNA, there are several examples of RNAs acting in other cellular contexts; for example, lncRNAs have been reported to have functions in regulation of protein activity, scaffolding for protein complexes, intercellular signaling through exosomes, and recombination, as reviewed elsewhere (Geisler and Collier, 2013). As little is currently known about actions of RNAs on other cellular components, it will be interesting to see what other functions are ascribed to RNAs in the future.

New Technologies for mRNA Transcriptomics

Although RNA-seq has the capacity to indiscriminately assess the full complement of RNA types (i.e., both coding and noncoding) found in a given cell or tissue, more focused methodologies are being developed for studying the protein-coding transcriptome, cutting down costs associated with unbiased sequencing. For example, Halvardson *et al.* (2013) have described a method that marries aspects of exome and RNA-seq to improve the detection of mRNA expressed at low levels. This method, termed ExomeRNAseq, first applies whole exome capture to cDNA, followed by conventional RNA-seq of the enriched transcript pool. Although this approach appears successful in detecting transcripts with low expression and identifying novel exons and splice isoforms, it can reduce quantification accuracy. An alternative way to enrich mRNA

prior to sequencing is the use of immobilized oligo-deoxythymidine to select polyadenylated RNAs, thereby removing highly abundant rRNA and non-polyadenylated transcripts such as ncRNA (Sims *et al.*, 2014). Such enrichment also increases the proportion of sequence reads that map across splice junctions, improving the discovery and identification of alternative splice variants. Current mRNA enrichment techniques facilitate RNA-seq experiments that can effectively define the components of the coding transcriptome of a particular cell or tissue, however, more research is required to develop experimental and computational techniques that provide more accurate quantification of transcripts for differential expression analysis.

Integrating Transcriptomics with Other Omics

The integration of genomics with transcriptomics, also termed functional genomics, has led to a better understanding of the relationship between genotypes and phenotypes, significantly impacting the fields of biology and medicine. However, more comprehensive approaches that also combine transcriptomics approaches such as RNA-seq with complementary proteomics technologies are required for deeper understanding of the relationship between genotypes and phenotypes. This commonly entails proteomics validation of predictions based on transcriptome data, and so differs from earlier implementations of proteogenomics, where protein predictions derived from reference genome sequence information are assessed using proteomics (Wang *et al.*, 2014).

Mass spectrometry technologies, notably high-throughput liquid chromatography–tandem mass spectrometry-based proteomics approaches, have been applied fruitfully on various fronts (Wang *et al.*, 2014; Woo *et al.*, 2013). At a foundational level, high-throughput proteomics information can assist considerably in ongoing annotation of both the transcriptome and the genome and, conversely, RNA-seq data, including transcript abundance and sequence variation and splicing variation, can improve protein identification in proteomics (Wang *et al.*, 2014). There are also many other potential applications, including computation of sample specific expression and identification of genomic variants (Woo *et al.*, 2013).

However, combining proteomics with transcriptomics data is complicated by the restricted correlations of these two omic spaces. Notably, with regard to identity, there are often non-linear relationships between a parental genomic sequence and its derivative RNAs and protein variants (if any), an obvious example being the ncRNAs, as discussed above. With regard to abundance, correlations are restricted by real biological divergence (Gawron *et al.*, 2014; Van Damme *et al.*, 2014; Vogel and Marcotte, 2012) as well as by current differences in detection limits in these spaces. Protein abundance is regulated not only by mRNA translation rates in both prokaryotes and eukaryotes, but also by posttranslational modifications of proteins that greatly influence protein degradation and turnover (Vogel and Marcotte, 2012). The half-life of proteins is controlled by various pathways such as, but not limited to, the ubiquitin and proteasome pathways. The presence or absence of posttranslation modifications (which cannot be predicted

by transcriptomics), such as phosphorylation, glycosylation, or ubiquitinylation, has a strong impact on protein stability, adding a further level of complexity. Together the composition and dynamic of the proteome is not deducible from functional genomics data and as a consequence, proteomics is an indispensable and complementary approach to transcriptomics.

While it is difficult to integrate the huge bodies of data that can arise from multiple different transcriptomic and proteomic datasets derived from different samples, a range of new bioinformatics tools are now emerging that make inroads into overcoming these problems, for example by methods that compress data size without loss of sensitivity by constructing more compact nonredundant datasets (Woo *et al.*, 2013). A more complete realization of proteogenomics, in which the three levels of DNA and epigenetic modifications, RNAs and their epitranscriptomic modifications, and proteins and their posttranslational modifications, are studied simultaneously in the process of conceptual and technical development and promises to be an important milestone in systems biology (Renuse *et al.*, 2011).

Conclusion

The advent of high-throughput sequencing technologies is providing unprecedented insights into the composition and complex interactions of the transcriptome. In the space of less than two decades, our understanding of the transcriptome has been transformed from a simplistic view that RNA species serve solely as intermediaries between DNA and protein, to one where interactions between protein-coding RNAs and a plethora of ncRNAs amplify the complexity of multicellular organisms. With future advances in sequencing technology and computational capacity, it is likely that the transcriptome will reveal itself to be both far more intricate and far more influential than ever before imagined.

The Advent of Mass Spectrometry-Based Proteomics in Systems Biology Research

Systems Biology and Proteomics

Systems biology aims to comprehensively describe complex biological processes as a network with nodes and edges (Ideker *et al.*, 2001). Nodes of such a network generally represent molecules such as proteins or genes, the edges generally represent their physical or functional interactions. The rearrangement of such a network following genetic or external (i.e., environmental) perturbations, explains how these perturbations result in a phenotype. According to this theory, by knowing the nodes, edges, and mechanisms underlying this network, it can be predicted how a phenotype results from the state of the network (Ideker *et al.*, 2001). This network-based approach is the rationale for systems biology efforts to study complex biological processes and complex diseases (Barabasi *et al.*, 2011). The approach has become possible due to the development of the so-called ‘-omics’ techniques and by the application of *in silico* modeling to biology. Among the ‘-omics’ technologies genomics has led the way by efficiently analyzing whole genomes and transcriptomes. Such analyses resulted in a defined list of genes (and thus proteins) that can be expressed from the respective genome, or in the network terminology the nodes of the network. Once the nodes are known, the next challenge is to understand how these nodes are connected by specific interactions, or edges, to produce the observed phenotypes. Especially in this next step, we believe that mass spectrometry-based proteomics will play a major role.

Genomics and transcriptomics are the archetype of an ‘-omics’ technique in terms of throughput, measurable nodes and accuracy. This is what proteomics aims to achieve for the proteome (Cox and Mann, 2007). Genomics has had an immense impact on biological research (Lander, 2011). However, the effectors of most biological processes are proteins, neither genes nor mRNA. Moreover, posttranslational modifications (PTMs), such as phosphorylation, are not accessible to genomic or transcriptomic techniques. Hence, when studying molecular networks using a systems biology approach, ideally the proteins and their quantities should be directly measured rather than inferred. In contrast to genomics that analyzes nucleic acids by sequencing, the analysis of the proteome faces several challenges that have hampered progress toward the ability of measuring all proteins simultaneously using a standardized workflow. First, proteins or peptides vary significantly in their size and physicochemical characteristics. For example, some proteins can consist of up to several thousand amino acids while others are very small. Membrane proteins are very hydrophobic, conversely very soluble or even charged proteins exist. Second, in contrast to four different nucleic bases, proteins are built of 20 different amino acids that each vary greatly in their charge, polarity, and size. Furthermore, many different PTMs of proteins further increase the

complexity. Third, the large difference in abundance of proteins makes analyzing the proteome very challenging. The measured protein abundances in cells range across 7 orders of magnitude (Beck *et al.*, 2011) and > 8 orders of magnitude in plasma (Shen *et al.*, 2005). The actual difference in abundance of proteins, especially in the plasma, is believed to exceed 10 orders of magnitude (Anderson and Anderson, 2002). Despite these outlined challenges, proteomics has experienced an immense advance in the last decade in terms of scope of the analyses and the accuracy, reliability and reproducibility of the results, as discussed below. Hence, proteomics has recently become a prime technology for systems biology studies.

To measure several hundreds or thousands of proteins in parallel and for a large number of samples mass spectrometry-based proteomics as we discuss it here is the current method of choice among the proteomics techniques. Mass spectrometers can also be coupled to a flow-cytometer that allows measuring at single cell resolution up to hundred different metal-labeled antibodies binding to individual cells and holds great promise for future systems biology studies (Bandura *et al.*, 2009; Bodenmiller *et al.*, 2012). Other analytical techniques such as ELISA, Western blotting, immunohistochemistry, or protein microarrays can also be used to measure protein abundances (Stoevesandt and Taussig, 2012). However, all of these techniques rely on antibodies or other affinity reagents that specifically recognize a certain epitope on the proteins. Although these affinity-based techniques show sometimes greater sensitivity and throughput capability than mass spectrometry-based proteomics, it is more challenging to scale up these methods to measure many hundreds or several thousand proteins in a highly multiplexed manner. Therefore, mass spectrometry-based proteomics has emerged as the best suitable technique to measure a certain system as comprehensively as possible. Hence, we will focus on liquid chromatography-coupled tandem mass spectrometry-based proteomics (LC-MS/MS) and show how this technique can provide data for systems biology studies.

Liquid Chromatography-Coupled Tandem Mass Spectrometry

Digestion of Proteins into Peptides

To identify and quantify a large number of proteins using a generic mass spectrometric method, proteins are digested into similarly sized peptides that are then measured. This approach is usually referred to as, ‘bottom-up’ proteomics, as opposed to analyzing the proteome ‘top-down,’ which analyzes the intact proteins using mass-spectrometry (reviewed in Catherman *et al.*, 2014). Because highly complex samples, such as a total cell lysate, cannot currently be measured efficiently using top

down proteomics, this approach will not be covered here. The digestion of proteins to peptides has practical advantages. Peptides are more similar in their masses and are therefore much easier to measure than different proteins by a liquid-chromatography (LC) coupled mass spectrometer. Moreover, a mixture of peptides is easier to handle and degrades less readily than proteins. Digestion into peptides is most commonly performed in a one-step digestion using trypsin, or a two-step protocol with trypsin and LysC (Glatter *et al.*, 2012; Wisniewski and Mann, 2012). The digestion can be performed in-gel (e.g., after SDS-PAGE gel electrophoresis) or in solution (Shevchenko *et al.*, 1996). Importantly, the digestion of the proteome into peptides comes at the cost of vastly increasing the complexity of the sample and of losing the connection between the peptide and the protein that is inferred from the identified peptides. The data generated on the peptide level need to be mapped onto the protein level to make statements about the protein contents of a sample, a process that has been termed 'protein inference' (Kuster *et al.*, 2005; Nesvizhskii and Aebersold, 2005). That this data analysis process is not trivial and can lead to differential results among labs has been shown in a cross-laboratory study (Bell *et al.*, 2009). The bottleneck in correct identification did not lie in the detection or fragmentation of peptides, but rather in the correct annotation and searching of the data. However, the protein search tools performing these annotations are constantly improving, making the annotation increasingly robust and automated (Cox and Mann, 2008; Eng *et al.*, 1994; Röst *et al.*, 2014). Importantly, robust strategies have been developed to control for the false-discovery rate using the target-decoy search strategy and by modeling the score distribution of false annotations (Elias and Gygi, 2007; Keller *et al.*, 2002). Besides the development of new mass spectrometers, the advancement of analysis tools has been a major contributor to the advent of mass spectrometry-based proteomics in the last decade.

Reducing the Complexity by Separation

The complexity of a sample to be measured can be reduced by pre-fractionation of the sample into different fractions that are analyzed independently. The measured data from these fractionated samples are then merged to obtain one dataset corresponding to the initial sample. Fractionation reduces greatly the complexity within the fractionated sample and thus increases the sensitivity and the number of analytes detected from the initial sample. The drawback of this procedure is the increased preparation and measurement time, and the risk of losing some of the peptides/proteins during the fractionation process. Different separation techniques have been used in bottom-up proteomics for proteins or peptides. One of the first pre-fractionation techniques separates proteins by mass or isoelectric point using gel electrophoresis. 2D-gels can separate proteins by size and isoelectric point. Separating peptides by their isoelectric point can also be performed in the so-called off-gel fractionation that allows omitting the elution of the peptides from the gel. In addition to the electrophoresis-based separation techniques chromatography is widely used to separate proteins or peptides according to their physico-chemical characteristics. For example cation-exchange (SCX),

size-exclusion (SEC) or reverse phase chromatography is used to separate the peptides or proteins according to their size, charge, or polarity, respectively. Importantly, the complexity can also be reduced by enriching for specific proteins/peptides that harbor specific characteristics. This is especially common when studying posttranslational modifications such as phosphorylation or ubiquitination (Bodenmiller *et al.*, 2007; Xu *et al.*, 2010). Also, the proteome of certain organelles or complexes can be enriched by biochemical techniques (Andersen *et al.*, 2005). Moreover, using tandem-affinity tags coupled to a protein of interest, it is possible to efficiently enrich specifically for protein interactors of that protein (Gingras *et al.*, 2007; Glatter *et al.*, 2009).

Pre-fractionation has been intensively used to detect or map proteomes of very complex samples, such as total cell lysate of human cells. However, the increased measurement time required by the analysis of fractionated samples is especially relevant when considering measuring many samples across different conditions in a systems biology study. Therefore, measuring many different samples comes usually at the cost of reducing the pre-fractionation steps and thus the limit of detection and the number of identified peptides. In addition to these pre-fractionations, peptides are usually separated directly before injection into the mass spectrometer. This is performed using a nano-flow liquid chromatography (LC) device linked to a direct electrospray introduction into the mass spectrometer. The most popular method is to separate the peptides during the LC by using reversed-phase chromatography. This on-line separation can also be increased to two dimensions as is performed in the so-called MudPIT approach (Link *et al.*, 1999).

Measurement of the Peptides by Mass Spectrometry

For peptide identification, tandem mass spectrometers generally perform the following sequence of steps: (1) they determine the mass to charge ratio (m/z) of a precursor ion in an MS1 spectrum, (2) they select specific precursor ions and subsequently fragment them in a collision cell, and (3) they measure the m/z of the product ions arising from this collision and record them in the form of a fragment ion or an MS2 spectrum. Various instruments suited for the different mass spectrometry approaches are available that differ with respect to their sensitivity, mass accuracy or working modes (Domon and Aebersold, 2010). The acquired data are then analyzed using software tools to obtain information indicating which peptides have been present in the sample and to some extent to infer their relative or absolute quantities. Different approaches to perform mass spectrometry-based proteomics and quantification are briefly introduced below (Figure 1).

Data-dependent acquisition

Shotgun or data-dependent acquisition (DDA) is currently the most widespread method in mass spectrometry-based proteomics. At a given time during the elution of the peptides from the LC-column, an MS1 spectrum is acquired by scanning for all precursor ions. From this MS1 spectrum, a subset of the detected precursors, usually those with the highest signal intensity, are selected, fragmented, and an MS2 spectrum is

Figure 1 Proteomic depth against data completeness for different mass spectrometry supported approaches. The proteomic depth (i.e., number of proteins measured) in a single injection versus data completeness (i.e., lower missing values) across many different complex samples for different mass spectrometry approaches is shown. These features have been estimated for a systems biology experiment quantifying the proteome of a total cell lysate across dozens of different samples. DDA, data-dependent acquisition; DIA, data-independent acquisition; SRM, selected-reaction monitoring.

acquired for each precursor. This process is repeated in many cycles during the elution of all of the peptides by the online liquid chromatography. The acquired MS2 spectra of individual precursor ions are compared to databases of *in silico* generated spectra (Cox and Mann, 2008; Eng *et al.*, 1994; Keller and Shteynberg, 2011). This allows the association of these spectra with their corresponding amino acid sequences. Today, state-of-the-art tandem mass spectrometers can identify over 30 000 peptides and about 4000 proteins per injection (Hebert *et al.*, 2014; Nagaraj *et al.*, 2012). Despite this impressive performance it has to be recognized that, in the case of complex proteomes, a much higher number of peptides is present in the samples than can be sequenced (Michalski *et al.*, 2011a). Because not all peptides can be measured, a stochastic step of selecting the precursor ions to be fragmented is performed and can result in missing values in between runs, if the same precursor ion is not measured. This problem can be partially alleviated by using inclusion lists (Schmidt *et al.*, 2008). The DDA approach is currently the most widely used method and especially suitable for discovery-driven studies such as mapping the proteome of a complex sample. As DDA is historically the oldest method, both instruments and analysis tools are very mature.

Targeted data acquisition or selected reaction monitoring

The most sensitive approach for measuring a proteome is the targeted data acquisition approach. The most prominent targeted acquisition approach is selected reaction monitoring (SRM), or synonymously multiple reaction monitoring (MRM). SRM is performed by measuring specific transitions by selecting a specific, predetermined precursor ion and a number of corresponding product ions. In contrast to DDA, the mass spectrometer is directed to selectively record these precursor-product ion transitions for a certain peptide. This greatly increases the specificity and sensitivity allowing SRM to detect peptides across 3–5 orders of magnitude (Anderson and

Hunter, 2006; Ebhardt *et al.*, 2012; Picotti *et al.*, 2009). In contrast to DDA, the number of proteins measured in one injection is much lower. Using optimized conditions, about 100 proteins can be measured in one multiplexed analysis run (Picotti and Aebersold, 2012). While in DDA a sample can be acquired without any prior knowledge, for SRM it has to be clearly defined which transitions ought to be measured. Therefore targeted proteomics is a conceptually very different way of performing proteomics because a list of transitions that will be measured has to be defined beforehand (Picotti *et al.*, 2010). Notably, a recently developed approach termed parallel reaction monitoring (PRM) omits the necessity of defining the product ions. In PRM, a certain precursor is selected as in SRM, but then a full MS2 spectrum is acquired (Gallien *et al.*, 2013). Hence, only a list of precursor masses to be selected has to be provided. For either method, once the signal of selected transitions has been acquired for a particular peptide, the data analysis is rather straight-forward and aided by dedicated software (MacLean *et al.*, 2010; Reiter *et al.*, 2011). As the mass spectrometer will measure at the right mass and elution time, measurements with no missing values are the norm.

Cross-laboratory validation of SRM showed very good reproducibility and ability of this technique to detect even μg per ml amounts of protein in plasma (Addona *et al.*, 2009). The targeted data acquisition approach is especially suitable if a set of several hundred proteins across many different samples need to be accurately quantified.

Data-independent acquisition

In the data-independent acquisition (DIA) approach, the proteome is mapped in a systematic way selecting reproducibly a range of precursors by defining a selection window in MS1. In contrast to the before mentioned approaches, where precursors are selected by a stochastic process (DDA) or by predefined lists (SRM and PRM), the DIA approach selects precursor ions in a systematic and comprehensive manner

(Venable *et al.*, 2004). There exist different DIA approaches selecting precursor ions in windows in MS1 ranging from one large window of 800 Da in MS^E (Plumb *et al.*, 2006), or smaller cycling windows of 10 Da (Venable *et al.*, 2004), or 25 Da in SWATH-MS (Gillet *et al.*, 2012), or as small as 2.5 Da in PAcFIC (Panchaud *et al.*, 2009). In DIA, all of the selected precursor ions are fragmented simultaneously and a whole MS/MS spectrum is recorded. This procedure generates a reproducible and comprehensive proteomic fingerprint of a sample, omitting any missing values on the side of the data acquisition. However, while selecting many precursors at the same time, the information is lost to which precursor the measured product ions are belonging to. Therefore, the analysis of DIA data has been especially challenging. Employing a targeted data analysis approach, it has recently become possible to annotate reliably DIA data also in very complex samples (Gillet *et al.*, 2012). This targeted analysis approach interrogates the acquired spectrum with spectral libraries, instead of annotating the spectrum using databases as in DDA (Gillet *et al.*, 2012). Spectral libraries consist of previously recorded signals of transitions, typically acquired and annotated to peptides and proteins by DDA. The SWATH-MS approach has been shown to be more sensitive than DDA in a complex sample, but a little less sensitive than SRM (Gillet *et al.*, 2012). Out of the different DIA approaches we will henceforth focus on SWATH-MS in this article as it shows the most interference free signal (Gillet *et al.*, 2012). As SWATH-MS is a recently developed technique, both the mass spectrometers and analysis tools have just been developed (Röst *et al.*, 2014). First studies mapping protein–protein interactions or identifying biomarkers with SWATH-MS show that the data completeness, i.e., the minimal number of missing values across datasets, of the measurement is very beneficial (Collins *et al.*, 2013; Lambert *et al.*, 2013; Liu *et al.*, 2013).

Quantification of Peptide Abundance

In addition to identifying the peptides present in a sample, the abundance of a peptide or protein across different samples needs to be compared. Mass spectrometry is a quantitative technique and the ion count of detected ions serves as a measure of the abundance of the respective peptides. Hence, the change in abundance of peptides between different samples can be quantified by relating their elicited signal. In order to obtain an accurate quantification, four different approaches are explained here (for a more comprehensive review see Bantscheff *et al.* (2012)). Most take advantage of the existence of stable isotopes. Isotopically different peptides differ in their mass because they contain a different number of neutrons and therefore are distinguishable by mass spectrometry. For example, a ‘heavy’ ¹³C₆ ¹⁵N₂ L-lysine shows an 8 Da mass shift from a ‘light’ ¹²C₆ ¹⁴N₂ L-lysine. However, these ‘heavy’ atoms, and by implication the peptides that contain them, have the same chemical properties as the corresponding ‘light’ peptides.

First, in label-free quantification the peptide intensity can be compared by counting the number of spectra generated by DDA (spectral counting). Alternatively, the area of apex of the signal peak can be compared by recording the corresponding

signal in either MS1 or MS2 while the peptide is eluting from the LC-column.

A second approach consists of spiking heavy peptides into the sample and measuring the ratio of the signal between light and heavy peptides. By this way differences in chromatography or peptide digestion between different samples are cancelled out and it is often used in SRM studies. For DDA, heavy reference peptides have been spiked into the samples in the form of a metabolically labeled proteome and termed super-SILAC (Geiger *et al.*, 2010).

In the third approach peptides are labeled chemically. The tags will add a certain mass to each peptide. This can be performed by using ICAT (isotope-coded affinity tags) in their light or heavy form (Gygi *et al.*, 1999), or with a range of other isotopic reagents (Bantscheff *et al.*, 2012). A variant of the isotope-based quantification approach is isobaric tagging exemplified by iTRAQ (isobaric Tags for Relative and Absolute Quantitation) or TMT (Tandem Mass Tags). For these isobaric tags, the precursor ions show the same mass in MS1, but in the MS2 spectrum the contribution of the different tags can be quantified (Ross *et al.*, 2004; Thompson *et al.*, 2003).

The fourth approach is based on metabolic labeling. Here, cells are grown in medium containing light or heavy nutrients, such as essential amino acids, that are incorporated into the proteins. The most common approach of metabolic labeling for proteins is termed SILAC (Stable isotope labeling by amino acids in cell culture) (Ong *et al.*, 2002).

In summary, there are many different ways of quantifying the signal acquired from a peptide (Bantscheff *et al.*, 2012). Accuracy and precision vary between these different approaches and need to be taken into account before performing or analyzing such experiments. Label-free quantification is for example directly affected by variations in the chromatography or instrument performance that affect the signal intensity. These variations can be efficiently cancelled out by using a labeling approach and thus quantifying and comparing peptides eluting at the same time. In addition to quantifying relative abundances, absolute quantification can be attempted. For absolute quantification typically the so-called AQUA peptides are spiked in at an exactly determined concentration (Gerber *et al.*, 2003). By spiking in a small set of reference peptides and by relating the relative abundance of the peptides using label-free quantification, accurate measurement for the remaining proteome can be obtained with reasonable costs and effort (Chang *et al.*, 2014; Ludwig *et al.*, 2012).

Systems Biology Application for High-Throughput Proteomics

Above, the major different implementations of mass spectrometry-based proteomics have been briefly outlined. In the remainder of this article, we summarize exemplary cases that employ these methods in systems biology studies. In the first part, the application of these techniques to conceptually different ways to study the proteome (i.e., mapping the nodes) is covered, showing the current state of the art. In the second part, three exemplary complex biological processes (i.e., cell cycle regulation) are highlighted to show the impact of

proteomics on systems biology studies in these selected biological processes.

Different Conceptual Approaches in Mass Spectrometry Based Proteomics

Mapping the nodes of a proteome

The major aim in the early phase of proteomics was to map the proteome of different species, organelles, or subproteomes (such as the phosphoproteome) in order to define the 'parts list' or, in systems biology terms, the network nodes of different organisms. In such studies for mapping a proteome, DDA has typically been used in combination with extensive pre-fractionation of the samples.

The genome-predicted proteome can now be mapped completely or to a very large extent with mass spectrometry-based proteomics. This has been, for example, shown for prokaryotes (Ahrens *et al.*, 2010; Schubert *et al.*, 2013) and *Saccharomyces cerevisiae*, where over 4000 proteins could be identified corresponding to a substantially complete proteome (de Godoy *et al.*, 2008; Hebert *et al.*, 2014). In human cell lines, about 10'000 proteins could be identified in different large-scale studies (Beck *et al.*, 2011; Geiger *et al.*, 2012; Moghaddas Gholami *et al.*, 2013; Munoz *et al.*, 2011; Nagaraj *et al.*, 2011), and finally two recent studies reported a first draft of the human proteome detected proteins for up to 92% of the annotated genes by analyzing many different tissues (Kim *et al.*, 2014; Wilhelm *et al.*, 2014). For targeted proteomics, the relevant information is for how many proteins SRM-assays have been developed. The PeptideAtlas is a community-based approach collecting this information and making it publicly available to support SRM studies (Deutsch *et al.*, 2008). SRM-assays have been deposited in the PeptideAtlas for >97% of the genome-predicted proteome of *S. cerevisiae* and *M. tuberculosis* (Picotti *et al.*, 2013; Schubert *et al.*, 2013) and SRM assays for the entire human proteome have been developed (unpublished). Hence, both with DDA and SRM the large majority of the genome-predicted proteome can be measured.

In addition to the genome-predicted proteome, there are many subproteomes consisting of post-translation modifications (PTMs) such as, for example, the phosphoproteome. The phosphoproteome is of considerable interest because phosphorylation events are key PTMs influencing the activity of many enzymes and proteins. The number of PTM identifications has so far increased without reaching saturation (Olsen and Mann, 2013). Here, a few examples of large studies mapping PTMs are listed: Phosphoproteomic studies have detected 54 755 phosphopeptides and 9287 phosphoproteins by analyzing different tissues in mouse and rat (Huttlin *et al.*, 2010; Lundby *et al.*, 2012b). 15 474 lysine acetylation events on 4541 proteins have been detected in 16 different rat tissues (Lundby *et al.*, 2012a). 6397 glycosites on 2352 proteins were identified in different mouse tissue and plasma (Zielinska *et al.*, 2010). Assessing the ubiquitinated proteome, two studies have detected 4000–5000 ubiquitinated proteins with 3–4 times the number of ubiquitylation sites (Kim *et al.*, 2011; Wagner *et al.*, 2011). Hence for many subproteomes, extremely large numbers of modified proteins could be detected. Because mass spectrometry based proteomics is often the only

technique able to measure these modifications, many of these modifications have been reported for the first time and their functional role needs still to be investigated. Hence, mapping these subproteomes is still largely in progress.

Organization of the proteome

Once a list of nodes has been defined, the next question, when performing a systems biology study, is how these nodes interact. This question can also be phrased as how the proteome is organized or structured in a network, and what type of interaction the edges represent. An important and biologically meaningful type of interaction is physical protein–protein interactions. Using tandem affinity purification coupled with mass spectrometry, physical protein–protein interactions can be efficiently mapped (Gingras *et al.*, 2007). This has been typically performed by DDA, but recent studies have successfully employed SWATH-MS (Collins *et al.*, 2013; Lambert *et al.*, 2013).

For example, two studies identified around 500 protein complexes that encompass 7 123 protein–protein interactions in yeast by analyzing complexes where the bait protein was affinity tagged by knock-in technology (Gavin *et al.*, 2006; Krogan *et al.*, 2006). As genetic manipulation is not so simple in mammalian cells different techniques have been used for large-scale mapping of protein–protein interactions. In mammalian cells, extensive biochemical separation identified 622 complexes consisting of 3006 proteins and 13 992 physical interactions (Havugimana *et al.*, 2012). Performing 3290 immunoprecipitation with 1796 different antibodies, over 11 000 proteins were identified and 430 000 interactions observed (Malovannaya *et al.*, 2011). Still it is likely that the complete interactome has not been mapped. It has been estimated that the yeast proteome contains in total about 18 000 binary interactions (Yu *et al.*, 2008). The human proteome is predicted to have about 130 000–650 000 binary interactions (Stumpf *et al.*, 2008; Venkatesan *et al.*, 2009). These estimates show the scope of mapping all the interactions. Notably, to map the binary interactions, but not complexes, alternative high throughput approaches exist. Yeast two-hybrid (Y2H) or protein complementation assay (PCA)-based methods have been shown to probe more efficiently for binary interactions, whereas mass spectrometry-based methods are superior for identifying complexes (Yu *et al.*, 2008). Therefore, to obtain a comprehensive picture of all interactions, the data obtained from different approaches need to be combined.

In contrast to the unbiased large-scale mapping approaches, affinity purification mass spectrometry (AP-MS) studies on specific set of proteins have been performed to focus on a particular biological process as shown here on some examples. Using AP-MS in yeast, interaction studies with several hundred baits can be performed, such as the interactome of 276 kinases and phosphatases that resulted in 1844 interactors (Breitkreutz *et al.*, 2010). In humans, interactome studies have so far been limited to smaller number of baits largely due to technical limitations in genetic engineering and culturing of mammalian cells. Nevertheless protein–protein interactions have been mapped for 11 proteins in the PP2A system (Glatter *et al.*, 2009), 74 deubiquitination enzymes (Sowa *et al.*, 2009), 32 proteins involved in autophagy (Behrends *et al.*, 2010), interactors of the 14-3-3 β scaffold

protein (Collins *et al.*, 2013), the human Hippo signaling pathway (Hauri *et al.*, 2013), or 57 human CMGC kinases (Varjosalo *et al.*, 2013). Usually these studies reported approximately 10 times the number of interacting proteins compared to the number of bait proteins tested. An exception to that rule is the scaffold protein 14-3-3 β that interacted with 567 proteins across different time points. These studies show that AP-MS can be efficiently used to study a protein–protein interaction network of choice.

Correlation of the proteome with the genome

A phenotype or disease is the result of the genetic predisposition in combination with environmental influences. Genetics has for decades successfully identified genes causative for, or associated with, disease or phenotypes. Recently, genetic studies have identified many variants associated to phenotypes for complex diseases in sequencing or genome-wide association studies (GWAS) (Lander, 2011). These genomic regions, in order to eventually elicit a phenotype, are expected to affect the proteomic network. This perturbed proteomic network then results in an observable phenotype. To understand thoroughly how the genotype-to-phenotype transformation is happening, we first have to understand how changes in the genotype affect the proteome. Therefore, correlation of protein levels to genomic loci has been performed to unravel these associations. By employing protein quantitative trait loci (pQTL) analysis, genomic loci that correlate with the protein levels of a certain protein are identified. These loci can be separated in cis-QTL loci in the vicinity of the encoded protein, or alternatively trans-QTL loci, located apart from the encoded gene. For such studies the accurate quantification across many different samples is needed. Therefore, these studies have been performed by DDA or SRM combined with accurate quantification approaches.

In yeast, the protein abundance of 48 proteins in 78 *S. cerevisiae* strains were measured and for the majority of proteins a protein QTL were detected (Picotti *et al.*, 2013). In humans, about 4000 proteins were quantified from 95 patients from the HapMap project, and 77 cis-pQTL loci identified (Wu *et al.*, 2013). 46 cis-QTL and 874 trans-QTL loci were identified for 396 proteins in murine liver from 97 different strains (Ghazalpour *et al.*, 2011). For 43% of these proteins, multiple pQTL loci were found. A recent study suggests that due to the limited sample size, these studies are probably greatly underpowered and many more QTL loci are likely to be discovered using single cell measurements (Albert *et al.*, 2014). Hence, this shows that many correlations between the genome and proteome likely exist and we are only beginning to unravel these relationships.

Correlation of the proteome with the phenotype

To eventually understand the genotype-to-phenotype transformation, the correlation between the proteome state and an associated phenotype also needs to be understood. Many proteomics studies correlate reported proteins or protein modifications to a specific phenotype. These correlations are often based on a strong mechanistic rationale how these proteins or modifications could affect the phenotype. Using state of the art statistical and modeling approaches, this can result in a mechanistic network with predictive ability (as an

example (Miraldi *et al.*, 2013)). Nevertheless, it has been very difficult to find for many diseases biomarkers that predict accurately and reliably the outcome or disease presence. In these so-called biomarker studies, proteins, protein modifications, or signatures that are predictive for a certain phenotype or disease are searched. Biomarker studies have been mainly performed in human body fluids (blood or urine), feces, or biopsies. One challenge in identifying biomarkers in these samples is the large abundance differences in human plasma of about 10 orders of magnitude (Anderson and Anderson, 2002) and the high degree of sample variability expected in plasma samples from an outbred population. Highly abundant proteins mask the potentially most interesting proteins. Therefore, most protein biomarkers so far were not identified by mass spectrometry based proteomics (Surinova *et al.*, 2011). In general it has proven very challenging to find new validated cancer biomarkers with any method (Diamandis, 2012). Biomarker discovery can be separated in a discovery and validation phase. In the discovery phase regulated proteins are identified in biopsies, tissue or model organisms, that are then validated by measuring the protein levels in plasma or other easily accessible fluids (Surinova *et al.*, 2011). Among the different mass spectrometry based techniques SRM and DIA are probably best suited for validating biomarkers. SRM shows the highest sensitivity, DIA only shows slightly less sensitivity but has the advantage that the acquired proteomic map can be re-interrogated afterwards. This is especially important for clinical samples where the sample amount is very limited. For SRM and DIA, assay libraries of plasma proteins have been generated to facilitate this approach in the future (Huttenhain *et al.*, 2013; Liu *et al.*, 2013). Future studies need to show if mass spectrometry based proteomics will be able to efficiently identify and validate novel clinical biomarkers.

Measuring dynamic proteomes

The above-mentioned approaches often result in the description of a static proteome. However, both the proteome and edges in biological networks are highly dynamic. Therefore, such data cannot explain the dynamics of a network, nor can they explain dynamic biochemical mechanisms. Therefore, time-dependent measurements of the proteome upon perturbation are needed and, if possible, should be linked to a phenotype (Bensimon *et al.*, 2012). Measuring time-dependent responses to different perturbation requires reliable quantification and a throughput at the largest possible scale. Only if samples can be measured in one or very few injections per sample the analysis of a sizeable number of conditions (e.g., at a scale of hundred conditions) becomes feasible. Therefore, it is important how many proteins are detectable and quantifiable in a single injection. A single injection of a yeast lysate can identify about 4000 proteins which correspond to a nearly complete proteome (Hebert *et al.*, 2014; Nagaraj *et al.*, 2012). Single injection in DDA or with SWATH-MS can detect over 2000 proteins in complex human samples (Michalski *et al.*, 2011b). Hence, also in very complex samples, several thousand proteins can now be reproducibly detected and quantified at a large throughput. Depending on the objectives of a particular project the appropriate acquisition approach needs to be chosen. Whereas with DDA typically a larger number of proteins can be detected, the data

completeness, i.e., lower missing values, over many samples is lower in DIA (Figure 1). In targeted proteomics, the sensitivity is higher but the number of proteins is limited to a few hundred proteins. Nevertheless, the number of measured proteins measured at high throughput can be far larger than any other proteomic or cell-biological technique. Examples of time-dependent proteomic studies have been already mentioned above (Collins *et al.*, 2013) or will be described below.

Exemplary Biological Processes Studied with Mass Spectrometry Based Systems Biology Studies

Three different biological processes have been chosen to briefly highlight how mass spectrometry based studies could contribute to systems biology studies in these respective areas. Cell cycle regulation was selected as a biological process where a large part of the proteome is expected to undergo a change, epidermal growth factor signaling (EGF) as an example for a clinically relevant signaling pathway, and central metabolism as an example how proteomic data can be combined with data from other ‘-omics’ approaches, such as metabolomics.

Cell cycle regulation

Every growing cell is undergoing cell division, a very complex process that requires complex regulatory mechanisms. Cell cycle regulation is clinically very relevant, as uncontrolled proliferation is a hallmark of cancer. To study the cell cycle in mammalian cells, there have been several comprehensive proteomic studies on protein abundance (Lane *et al.*, 2013; Ly *et al.*, 2014; Olsen *et al.*, 2010), sub-proteomes such as proteins binding to the chromosomes (Ohta *et al.*, 2010), protein–protein interactions with three different cyclins (Pagliuca *et al.*, 2011), or the change in the phosphoproteome (Dephoure *et al.*, 2008; Ly *et al.*, 2014; Olsen *et al.*, 2010). The amount of proteins that change their abundance in a cell-cycle dependent manner more than twofold, has been reported to be up to 40% in the different studies corresponding to 2857 proteins. Even more pronounced is the amount of regulated phosphosites that reaches 50% of the recorded sites, corresponding to approximately 20 000 regulated sites. This extensive degree of regulation shows that profound changes are happening while cells are dividing. Despite having a good understanding of the cell cycle, we currently cannot annotate the exact role and implication of all these regulated proteins or protein modifications. This example shows how unbiased studies such as mass spectrometry-based proteomics can identify putative new regulators that could be further analyzed, or help in better understanding the effect of this biological process on cells.

EGFR signaling pathway

Signaling by growth factors such as Epidermal growth factor (EGF) is a crucial signaling pathway for cancer. Because of its clinical relevance, a lot of studies have been performed to understand this signaling pathway in detail. Extensive cross-talk and the complexity of these pathways however make it a very challenging task.

In 2004, temporal analysis of phosphorylation on up to 202 phosphoproteins upon EGF stimulation could be

measured (Blagoev *et al.*, 2004; Zhang *et al.*, 2005). The difference between stimulation by EGF and the closely related platelet-derived growth factor (PDGF) pathway was tested (Kratchmarova *et al.*, 2005). A later study detected 6600 phosphorylation sites on 2244 phosphoproteins, where 14% of the phosphorylation sites were shown to be regulated upon EGFR signaling (Olsen *et al.*, 2006). To test the influence of other proteins on EGFR signaling pathway, 332 phosphopeptides have been monitored upon overexpression of HER2, a receptor interacting with EGFR (Wolf-Yadlin *et al.*, 2006). It was shown that proteins with a role in migration are increasingly phosphorylated. This correlated well with the increased migratory behavior of these HER2 overexpressing cells. EGFR signaling could also be assessed in clinical samples of different patient-derived cancer cell lines (Rikova *et al.*, 2007), or recently using Glioma xenografts (Johnson *et al.*, 2012). In these clinical samples it was possible to detect differentially expressed proteins and phosphorylation events that could identify signatures for poor survival.

Also protein interaction networks in this system have been analyzed. As an example, 90 interactors for Grb2, a downstream target in EGFR signaling, were monitored using SRM following affinity purification in a time course after EGF stimulation (Bisson *et al.*, 2011). Out of these 90 proteins, 21 proteins were found to be interacting differentially depending on six different growth factors and showing time-dependent complex formation upon signaling (Bisson *et al.*, 2011). A later study determined the specific interactome for lung-cancer cells containing a mutated EGF-Receptor (Li *et al.*, 2013). This was combined with functional RNAi-screening and could propose different drugs to overcome the resistance caused by these mutations.

The example with EGFR signaling shows how in less than a decade, we have greatly advanced in our ability to characterize in increasing detail a signaling pathway such as EGFR signaling using mass spectrometry based proteomics, even in clinical samples.

Central metabolism

Metabolism is arguably the biological process in systems biology where the understanding is most advanced. Decades of work on metabolic pathways and the very extensive understanding of the underlying chemistry have made metabolic pathways to a large extent known, as well as their enzymes (Feist *et al.*, 2009; Thiele *et al.*, 2013). Metabolism is clinically relevant for many metabolic diseases such as obesity and diabetes but also implicated in cancer (Currie *et al.*, 2013). Another advantage of studying this biological system with proteomics is that metabolomics is able to measure many metabolites and determine fluxes of the different pathways that can be correlated to the proteomic data. This has been performed, for example, in a study where 199 proteins acting in yeast central metabolism were monitored by SRM on abundance level across different growth conditions (Costenoble *et al.*, 2011). A large fraction of the selected proteins (144 out of 199) changed considerably depending on different growth conditions. Interestingly, this study showed that proteins are still expressed even when they are not needed under the cellular state tested. Only about half of the proteins changed their expression more than twofold if the cell was shifted to a state where the specific proteins were unnecessary,

showing an unexpected stability of protein levels. This study was then extended to measuring phosphorylation status of 35 of these enzymes in these conditions (Oliveira *et al.*, 2012).

In another example, 144 proteins in two different mouse strains have been analyzed in murine liver under 12 different conditions in response to high-fat diet (Sabido *et al.*, 2013). It could be determined how >30 proteins responded differently in the two different strains to the same change in diet after 6 weeks. The study shows how the effect of perturbations can vary in an organism depending on its genotypic background. Hence, both the genotypic and environmental effect on a phenotype can be assessed and ideally be delineated. This is eventually what systems biology aims for (Ideker *et al.*, 2001). Therefore, these studies show that using mass spectrometry-based proteomics, we are advancing toward this idea of systems biology at great pace.

Outlook

As shown above, and highlighted with some biological processes as examples, we think that the impact of mass spectrometry-based proteomics on systems biology is likely to be profound. Most cell-biological processes have been discovered before the advent of mass spectrometry-based proteomics, but the current unique capabilities of proteomics, as briefly outlined in this article, promise to have a great impact on understanding biological processes in a more comprehensive way within the context of the living cell. Similarly as for genomics, we expect proteomics to change the field of biology and in particular systems biology greatly.

As a result of a decade of rapid development in the field of mass spectrometry techniques, the majority of the human proteome and complete proteomes for smaller organisms can now be reliably measured. Within the last decade, DDA has immensely increased its capabilities and DIA and targeted approaches have been developed. All of these approaches can measure biological samples at an ever larger scale, with better reproducibility and accuracy. How will the development of mass spectrometry-based proteomics continue? Besides further development of instrumentation, we envisage mass spectrometry-based proteomics to become more widely used in the next years, due to the robust implementation of techniques and advances in software tools. Rather than being mainly run by expert research groups in dedicated mass spectrometry environments, as is the case today, proteomics will likely extend to other labs of other disciplines and many more institutions. As QPCR, Western Blotting, FACS or sequencing is now used by many non technology-development labs, mass spectrometry-based proteomics will also become widespread in a similar manner. This will increase the number and breadth of biological processes analyzed from the few well-studied biological processes that have been used to date in proof-of-concept studies. Key for the successful popularization are robust and open-source pipelines and resources. If successful, this will likely result in an immense boost of proteomic data that then can be used in systems biology approaches such as generating predictive and quantitative model of biological processes.

There are some key considerations that should be considered when starting on a proteomics-based systems biology study. Importantly, a good compromise between proteomic depth, sample throughput and reproducibility has to be found (see also Figure 1). This implies defining the best proteomic acquisition approach and labeling strategy. Furthermore, it is crucial to ensure that the proteins or modifications of interest can reliably be measured. Some classes of proteins (e.g., membrane proteins) or low abundance proteins still require tailored pre-fractionation approaches. When comparing the data across many samples, it is crucial to have a robustly working instrument setup that can acquire data with very few missing values as many missing values will make a subsequent systems analysis and comparison cumbersome.

Measuring protein levels, protein modifications, and interactions at an unprecedented scale and precision will boost the systems biology approach that relies on quantitative and large-scale data. By generating network models based on proteomic data and containing PTMs, these models should become more accurate and predictive and lead to an ever better understanding. Linking the proteomic data to data from metabolomics, genomics and different phenotypes is expected to increase greatly our understanding how the genotype to phenotype transformation takes place. Hence, such network models of biological processes could lead to a thorough understanding of how genetic or environmental perturbations affect complex biological processes and eventually lead to complex diseases.

Introduction to Posttranslational Modifications

Many proteins are posttranslationally modified and it is those modifications and their interplay that often determine the function, interaction, and physio-chemical properties of these proteins. A posttranslational modification (PTM) is the covalent attachment of a chemical group to a protein after protein synthesis or the proteolytic removal of a signal peptide after cellular localization. More than 300 different PTMs are believed to exist (Husi and Grant, 2001), however, several of these modifications can be introduced during conventional sample preparation for proteomics applications. It is therefore of utmost importance to optimize sample preparation procedures for proteomics workflows in such a way that most of these modifications can be avoided in order to decrease sample complexity and eliminate nonbiological noise. Of these artefactual modifications, oxidation of methionine, carbamylation, acetylation, and formylation are among the most frequent, making these difficult to study when occurring naturally if no precautions are taken. For example, in a recent study it was found that acetic acid can induce a significant amount of lysine acetylation (Choudhary *et al.*, 2009) and therefore acetic acid should be avoided in studies aiming at characterizing the acetylome.

Below is given an introduction to the characterization of phosphorylated proteins by mass spectrometric methods. Not only does protein phosphorylation have a very substantial impact on cellular activity, we are able to detect and analyse it on a high-throughput basis; this offers an excellent opportunity to drill very deeply into the set of phosphorylated proteins and link this to biology. This is an important benefit; as we probe ever deeper into the PTMome, it becomes clear that PTMs are very widely distributed, and it is therefore necessary to have a correspondingly large-scale view of their distribution and dynamics in order to fully understand their function. In the case of phosphorylation, its amenity to analysis and evident biological importance create an attractive opportunity for proteomics. We focus below on the methods most commonly used to assess phosphorylation in proteomics studies, and the application of these in tissue or primary cell-based contexts, with their particular obstacles.

Protein Phosphorylation

Eukaryotic cells are highly dynamic, needing to respond effectively to alterations in the extracellular environment in order to maintain their basic function. One of the primary mechanisms by which cells respond to environmental stimuli is via protein phosphorylation and intracellular signaling, whereby nucleotide-derived phosphate (PO_4^{3-}) groups are added or subtracted from specific residues within proteins through the action of protein kinases or phosphatases, respectively. The amino acid residues targeted are specifically

serine(S), threonine(T), or tyrosine(Y) (in eukaryotes; prokaryotes also display phosphorylation at other residues, including histidine, asparagine, aspartic acid (Fuhrmann *et al.*, 2009; Wagner and Vu, 2000), and arginine (Fuhrmann *et al.*, 2009)) though as detection and interpretation methods become more sensitive and accurate, more residues are being implicated as targets of phosphorylation. Histidine is one such amino acid residue, with numerous reports of its presence in eukaryotic systems (Klump and Kriegelstein, 2009; Klump *et al.*, 2009), though there is as not yet enough evidence to say whether it is as widespread or has as substantial an impact as S, T, or Y phosphorylation due to the technical difficulties in the analysis of histidine phosphorylation.

The addition of phosphate is able to modify the structure, activity, interaction, or localization of the target protein to achieve a particular function, whether as a direct functional consequence (e.g., conformational change (Garza *et al.*, 2010)) or as part of a larger signaling cascade (such as is found in mitogen-activated protein kinases (Shaul and Seger, 2005)). On a chemical basis, the addition of phosphate has several effects, these primarily comprising the introduction of negative charge and hydrophilicity to the relevant region of the protein in question. These in turn may have several effects on the tertiary structure, the compartmentalization and/or interactions of the protein; for instance, the decreased hydrophobicity of the phosphorylated protein can reduce the degree to which it is membrane-associated (Ladokhin and White, 2001). Similarly, the increased negative charge imparted can impact on a protein's ability to bind to interaction partners (Joughin *et al.*, 2005; Groban *et al.*, 2006; Woods *et al.*, 2008; Woods and Ferre, 2005).

Phosphorylation pathways have been demonstrated to regulate a host of processes, both physiological and pathophysiological, and our understanding of them is therefore central to our understanding of how cell function is controlled in health and disease. Phosphoproteomics (Larsen *et al.*, 2001) is a relative new field within proteomics aimed at performing large-scale characterization of phosphorylated proteins present in a biological sample at a given time, in order to achieve a global understanding of phosphorylation-regulated signaling. Compared to conventional characterization of protein phosphorylation such as Western blotting (Gorog *et al.*, 2009; Obal *et al.*, 2005), phosphoproteomics, combined with efficient quantitative methods, offer a highly efficient and unbiased characterization of a large subset of proteins inside a cell and this in turn enable the efficient characterization of various cellular pathways and the discovery of novel members of such pathways. This is potentially very important in drug development as many targets for therapeutic intervention are kinases (Lapenna and Giordano, 2009).

Today, phosphoproteomics is typically performed using highly efficient phosphopeptide enrichment techniques in combination with mass spectrometry (MS), which has improved tremendously in sensitivity, dynamic range, and

accuracy in recent years. The success achieved in performing phosphoproteomics, especially when characterizing lower amounts of sample material (<1 mg) is to a large extent dependent on the efficiency of the phosphopeptide enrichment strategy and efficient fragmentation of phosphopeptides in the subsequent MS analysis, which together allow efficient identification and quantification of phosphopeptides. A number of research groups have worked extensively with developing novel methods for selective isolation of phosphopeptides prior to MS analysis, which have today resulted in multiple strategies for their isolation. Below are described some of the most commonly used ones for phosphopeptide enrichment.

Phosphopeptide Enrichment

Phosphopeptides, derived from proteins by proteolysis, are rarely detected when performing normal liquid chromatography coupled to tandem MS (LC-MS/MS) shotgun proteomics experiments. This is due to low stoichiometry of many phosphorylation sites on proteins, a generally low abundance of the phosphoproteins involved in signaling pathways (e.g., kinases and phosphatases) and a general lower signal intensity of phosphorylated peptides – especially multiply phosphorylated peptides – if analyzed by MS in the presence of non-modified peptides. Therefore, phosphopeptides must be enriched prior to LC-MS/MS. Numerous strategies for phosphopeptide enrichment have been developed over the last decade, including beta-elimination coupled to affinity purification (McLachlin and Chait, 2003; Oda *et al.*, 2001), phosphoramidate chemistry (Zhou *et al.*, 2001), immobilized metal affinity chromatography (IMAC) (Li and Dass, 1999; Neville *et al.*, 1997; Posewitz and Tempst, 1999), titanium dioxide (TiO₂) chromatography (Kuroda *et al.*, 2004; Larsen *et al.*, 2005; Pinkse *et al.*, 2004; Sano and Nakamura, 2004), sequential elution from IMAC (SIMAC) (Thingholm *et al.*, 2008), or antibody pull-down (e.g., immunoprecipitation Schmelzle *et al.*, 2006). Of these strategies, the most used are IMAC, TiO₂, and antibody pull-down of tyrosine phosphorylated peptides.

IMAC was first used for enrichment of phosphopeptides in 1997 (Neville *et al.*, 1997) and has for many years been the method of choice for enrichment of phosphopeptides from peptide mixtures. When performing IMAC, the phosphopeptides are reversibly bound to a chelating material containing metal ions, which selectively bind the phosphate group. The most commonly used metal ions are iron (Dubrovskaya and Souchelnytskyi, 2005) or gallium (Aryal *et al.*, 2008); however, Ti⁴⁺ have recently been shown to be promising for phosphopeptide enrichment (Zhou *et al.*, 2008). Phosphopeptides are normally bound to the IMAC material in an acidic solution containing organic solvent to prevent nonspecific binding to the material, and are subsequently eluted from the material using high or low pH, metal chelators such as ethylenediaminetetraacetate (EDTA), or buffers including molecules that interfere with the binding between the metal ion and the phosphate group, such as phosphoric acid or phosphate buffer. Despite the wide use of IMAC, several shortcomings have been reported, including incompatibility with several

common biological reagents (including EDTA and alkaline metal salts) (Jensen and Larsen, 2007), lower specificity when working with more complex samples (McNulty and Annan, 2009), selective binding of acidic peptides, and its preference for enriching multiply phosphorylated peptides (Jensen and Larsen, 2007). The latter shortcoming was actively used in the development of the SIMAC strategy (Thingholm *et al.*, 2008) where mono-phosphorylated peptides could be separated from multiply phosphorylated peptides by eluting the mono-phosphorylated and unmodified peptides off the IMAC material using 1% TFA (trifluoroacetic acid). The multiply phosphorylated peptides could then subsequently be eluted with high pH. The mono-phosphorylated and unmodified fraction was further purified using TiO₂ chromatography.

The current most widely used phosphopeptide enrichment technique is TiO₂ chromatography, first reported in a proteomic setting in 2004 (Kuroda *et al.*, 2004; Pinkse *et al.*, 2004; Sano and Nakamura, 2004) and later improved by Larsen *et al.* (Larsen *et al.*, 2005; Jensen and Larsen, 2007; Thingholm *et al.*, 2006). TiO₂ enrichment is based on the interaction between the negatively charged phosphate group and the metal oxide. The exact molecular mechanisms for this binding are unclear, though it is suggested to be a bridging bi-dentate formation (Larsen *et al.*, 2005; Michels *et al.*, 2000). The conditions under which maximally efficient phosphopeptide binding is achieved has been the subject of much investigation and are known with a high degree of confidence. As with IMAC, TiO₂ originally was found to bind a large number of acidic peptides (Pinkse *et al.*, 2004). This effect is significantly reduced by inclusion of a multifunctional acid such as dihydroxy benzoic acid (DHB) (Larsen *et al.*, 2005), phthalic acid (Thingholm *et al.*, 2006), glycolic acid (Jensen and Larsen, 2007), or lactic acid (Sugiyama *et al.*, 2007) to the enrichment media as a non-phosphopeptide excluder. As a result, loading and elution conditions for TiO₂ are very specific, where acidic loading buffers show reduced nonspecific interactions from negatively charged, non-phosphorylated peptides and basic elution conditions allow for release of the phosphopeptides from the chromatographic material. However, the exact buffers used for TiO₂ chromatography can vary depending on the TiO₂ material used, since many different TiO₂ materials can be produced.

Enrichment of phosphopeptides by the above-mentioned methods is not inherently biased toward serine, threonine, or tyrosine events, but the low abundance nature of tyrosine phosphorylation means that specific enrichment strategies must be adopted to reliably and reproducibly detect it. Even though accounting for only a small proportion of phosphorylated residues (conventionally quoted as between 1% and 5% (Thingholm *et al.*, 2009), experimental data vary considerably (Grimsrud *et al.*, 2010; Rogers and Foster 2009; Boersemma *et al.*, 2009; Rikova *et al.*, 2007)). Tyrosine phosphorylation is biologically important, as exemplified by receptor tyrosine kinases (RTK), the first step in many signaling cascades (Dengjel *et al.*, 2009). Acting as cell surface receptors, the numerous classes of RTK are activated by cytokines and growth factors, enabling early signal transmission within the cell. As such, phosphotyrosine residues are often specifically investigated, using an antibody approach or as an adjunct to a global phosphoproteomic approach (Villén *et al.*, 2007).

Monoclonal antibodies directed against phosphotyrosine are effective and readily available, and are the most common way to probe the phosphotyrosine proteome. The same is not true of phosphoserine or phosphothreonine, as the relatively less characteristic structures of these residues decrease the specificity of antibody methodologies (Gronborg *et al.*, 2002). Antibody-based methods are limited by the requirement for relatively large amounts of protein (typically of the order of 5–10 mg, as compared to many global phosphoproteomic experiment, which run with closer to 1 mg of protein), and are subject to similar levels of interference from non-target peptides as is observed with affinity-based chromatographic methods. An interesting corollary of these antibody-based experiments is that as more of them are performed, with more sensitive MS techniques and yet uniformly large sample amounts, investigators are able to probe ever deeper into the low abundance region of the phosphotyrosine proteome, such that a recent publication reported over 1100 unique pTyr sites (Boersema *et al.*, 2010). This result raises the question of whether this level of tyrosine phosphorylation represents 1–2% of a total cellular phosphoproteome of about 50 000–100 000, or whether the proportion of tyrosine phosphorylation is in fact lower than expected. PhosphositePlus, one of the largest databases of phosphorylation data, currently lists ~240 000 phosphorylation sites (Hornbeck *et al.*, 2012), and the pool of identified sites increases regularly, so it is entirely possible that the total cellular phosphoproteome is much larger than previously thought.

As is the case for any enrichment strategy, the decision to use IMAC, TiO₂ chromatography, or any of the above-mentioned approaches, either alone or in combination, will depend on the type of sample used, amount of starting material, and the desired outcomes of the workflow in question (Gates *et al.*, 2010). Furthermore, a study comparing phosphoramidate chemistry, TiO₂, and IMAC enrichments showed that no single method for phosphopeptide enrichment is able to identify all segments of the phosphoproteome, but that each approach documented overlapping but largely distinct populations (Bodenmiller *et al.*, 2007), suggesting that a combination of approaches is optimal; this is not surprising, as each of the three methods binds to phosphopeptides differently. Since the mass spectrometer has a limited analytical performance compared to the theoretical number of phosphopeptides present, another reason for the poor overlap could be under-sampling. Also, as with all comparisons made of biological methods, if one cannot perform each method to perfection, the result of such a comparison will differ depending on the person performing the experiments.

Large-Scale Phosphoproteomics Strategies

All proteomic studies, regardless of PTMs, rely on making samples for analysis as simple as possible in order to aid detection, thereby avoiding undersampling and increasing the coverage of the analytes. This is achieved using chromatographic fractionation, a conceptually simple operation whereby peptides are loaded onto a column of a solid stationary phase with a defined surface material, with which they interact and are retained. A mobile phase containing a solvent,

Figure 1 Examples of common large-scale phosphoproteomic strategies.

which reduces the strength of peptide-column interaction, is then applied to the stationary phase in an increasing gradient. The result is a gradual elution of peptides in a manner dependent on the degree of initial interaction. Several solid phases can be used effectively for phosphopeptide separation, though strong cation exchange (SCX) and hydrophilic interaction liquid chromatography (HILIC) are the most commonly used today (see overview of the most frequently used large-scale phosphoproteomics strategies in Figure 1). SCX chromatography involves allowing peptides to bind to a negatively charged resin followed by elution on an increasing gradient of salt (mobile phase), such that peptides with relatively lower charge states and therefore weaker interaction with the column elute earlier than those with strong interaction (Villén *et al.*, 2007; Gan *et al.*, 2008; Villén and Gygi, 2008). SCX is primarily a charge-state based separation, whereas HILIC, in contrast, is based purely on hydrophilicity in a directly orthogonal fashion to standard reversed-phase liquid chromatography (RP-LC) separation (Boersema *et al.*, 2008; Gilar *et al.*, 2005). When using HILIC, peptides are loaded in high concentrations of organic solvent (typically acetonitrile; mobile phase) with peptide hydrophilicity determining the strength of interaction with the stationary phase. Phosphopeptides, having an increased hydrophilic character due to the phosphate group, are retained on the column and eluted in decreasing concentrations of the organic solvent (McNulty and Annan 2009; Boersema *et al.*, 2008). These methods can, however, have some drawbacks; for example, the high salt mobile phase used for SCX chromatography is directly compatible with TiO₂ chromatography whereas a peptide cleaning up step might be needed for subsequent IMAC purification. In contrast, cleanup is not required for HILIC and this fractionation method is therefore directly compatible with TiO₂ and IMAC. A third fractionation procedure is electrostatic repulsion-hydrophilic interaction liquid chromatography (ERLIC (Zarei *et al.*, 2011)). This has been shown to

outperform SCX-IMAC, and also be able to enrich phosphopeptides and perform adequate separation in a single step (Gan *et al.*, 2008). A direct comparison between ERLIC and TiO₂ enrichment coupled with any kind of chromatography has not been performed.

Most of these fractionation methods are performed prior to the phosphopeptide enrichment step, which, if not used in an automated setup, is very labor intensive and could result in unwanted losses or poor enrichment of phosphopeptides due to suboptimal material/resin ratios (see below). Recently, a couple of large-scale phosphoproteomics strategies have been developed where the phosphopeptide enrichment is performed as the first step and then the purified phosphopeptides are further fractionated using other methods. For example, Ficarro *et al.* (2011) introduced the use of IMAC combined with a three-dimensional separation employing high pH RP, strong anion exchange (SAX), and low pH RP to increase the number of phosphopeptides from low amount of material (Ficarro *et al.*, 2011). In addition, Engholm-Keller *et al.* (2012) introduced the TiSH method involving an initial TiO₂ enrichment using an optimized TiO₂ beads: sample ratio (the TiO₂ beads: sample ratio has a substantial influence on the selectivity of the phosphopeptide enrichment) to enrich 'all' phosphopeptides in the sample. After enrichment, SIMAC was used to separate the multiply phosphorylated and mono-phosphorylated peptides from each other, followed by direct LC-MS/MS of the multiply phosphorylated fraction and HILIC separation of the mono-phosphorylated fraction prior to LC-MS/MS. The TiSH method yielded reproducibly more than 94% pure phosphopeptides from a complex sample and on an average 6500 unique phosphopeptides from 300 µg of starting material (Engholm-Keller *et al.*, 2012).

All these large-scale phosphoproteomics strategies mentioned above have been applied successfully to document the phosphoproteome of various mature cell types, including renal collecting duct cells (Rinschen *et al.*, 2010; Gunaratne *et al.*, 2010) and tissues such as intact liver (Villén *et al.*, 2007) and the mouse brain (e.g., Jedrychowski *et al.*, 2011; Palmisano *et al.*, 2012). Investigations on immortal cell lines are even more numerous and varied in their enrichment and fractionation approaches (Beausoleil *et al.*, 2004; Li *et al.*, 2007; Dephore *et al.*, 2008; Zhai *et al.*, 2008; Grimsrud *et al.*, 2009; Swaney *et al.*, 2009). However, here the amount of starting material in many cases is so high that any strategy for large-scale phosphoproteomics will be applicable. Again, as with phosphopeptide enrichment, it seems that orthogonal approaches will yield improved coverage of the phosphoproteome (Boersema *et al.*, 2007, 2008; Gilar *et al.*, 2005; Yates *et al.*, 2009).

Phosphopeptide Fragmentation

Tandem MS strategies for phosphoproteomics, when performed in a high-throughput manner, are based around fragmenting, sequencing, and identifying as many peptides as possible, as quickly as possible. It could be said that the rate-limiting step of phosphoproteomics is MS, in that the complexity of cell lysates usually means that only ~10–50% of a given sample will be sequenced and identified in any one

analysis, typically resulting in relatively low reproducibility between analyses. With these considerations in mind, an MS capable of as many fragmentation events as possible per unit time is preferable. Commonly, after enrichment of phosphopeptides they are sequenced by various fragmentation strategies, such as collision induced dissociation (CID) (McReynolds and Anbar 1977), phosphorylation directed MS³ (pdMS³) (Beausoleil *et al.*, 2004), multi-stage-activation (MSA) (Schroeder *et al.*, 2004), higher energy collisional dissociation (HCD) (Olsen *et al.*, 2007), or electron transfer dissociation (ETD) (Syka *et al.*, 2004). CID fragmentation frequently results in the loss of phosphoric acid from phosphopeptides with serine and threonine phosphorylation as the first fragmentation event and consequently little fragmentation of the peptide backbone to support the identification of the peptide sequence and phosphosite assignment. PdMS³ and MSA are two fragmentation strategies which take advantages of the loss of phosphoric acid observed in CID with concomitant selection of the signal originating from the loss of phosphoric acid for a subsequent fragmentation. Whereas pdMS³ provide the fragment ion spectrum from the signal originating from the loss of phosphoric acid, MSA is a sum of the fragment ions derived from the MSMS and MS³ fragmentations. The disadvantage of using pdMS³ is that the MS instrument needs to collect another ion-package which is associated with loss of analysis time. In addition, pdMS³ need high-intensity parent ion signals, as the peptide identification is based on the fragmentation of a selected daughter ion which will result in low signal intensity of the fragment ions.

Theoretically, MSA should provide higher sequence coverage than CID and pdMS³ for phosphopeptides; however, this is still debated and opposing reports exist on the subject (Ting *et al.*, 2011; Macek *et al.*, 2006). In contrast, HCD has been shown to be very efficient for phosphopeptides; however it is highly debated in the literature if HCD is better than MSA and CID for phosphopeptide sequencing (Jedrychowski *et al.*, 2011; Frese *et al.*, 2011; Nagaraj *et al.*, 2010). In our hands, HCD seems to provide a higher identification rate for phosphopeptides, especially singly phosphorylated peptides (Larsen MR, unpublished results), which we believe could be due to ion collision in the HCD cell that could result in multiple fragmentations per peptide molecule, with the initial loss of phosphoric acid followed by substantial backbone fragmentation. Loss of phosphoric acid is therefore not observed for singly phosphorylated peptides but mainly for multiply phosphorylated peptides (Larsen MR, unpublished results). A comparison of the fragmentation of a singly phosphorylated peptide is shown in Figure 2. Here, phosphopeptides were labeled with iTRAQ 4 plex reagents and subsequently purified using TiO₂ chromatography and analyzed by MSA and HCD. The selected peptide is AAAGPGAALSPR from PHD finger protein 10, where the serine is phosphorylated and the N-terminal labeled with iTRAQ. Figure 2(a) illustrates the fragmentation pattern obtained using MSA fragmentation and Figure 2(b) illustrates the fragmentation pattern using HCD. The main differences between these two spectra are the complete loss of phosphoric acid from the phosphoserine in the HCD spectrum making the site localization relatively straight forward, the low level of proline-directed fragmentation in HCD, and the abundant low mass signals in HCD compared to MSA.

Figure 2 Fragmentation of phosphorylated peptides using different fragmentation strategies. (a) Fragmentation pattern obtained using MSA of a peptide from PHD finger protein 10, where the serine is phosphorylated and the N-terminal labeled with iTRAQ. (b) Fragmentation pattern of the same peptide obtained using HCD fragmentation.

ETD has also been used in phosphoproteomics studies as this fragmentation technique does not result in any loss of phosphoric acid from peptides carrying serine and threonine

phosphorylation (Chi *et al.*, 2007). However, the speed of ETD is generally low, resulting in fewer phosphopeptide identifications and the efficiency of fragmentation is highest for

peptides carrying more than two charges, which are not commonly observed in phosphoproteomics studies as trypsin is normally employed as the protease.

Quantitative Phosphoproteomics

A substantial amount of effort in phosphoproteomics is devoted to quantification – obviously, a binary 'present or absent' phosphorylation assessment is simplistic. A biological effect can be produced without phosphorylating every member of a protein pool, and in these cases it is the relative degree of phosphorylation that is critical. Fortunately, this is comparatively easy to investigate, depending on the nature of the analysis. Strategies for quantitative phosphoproteomics have recently been reviewed (e.g., [Palmisano and Thingholm, 2010](#)) and a detailed description of all the various strategies will not be given here. Briefly, phosphopeptides can be quantified using metabolic labeling employing either ^{15}N ([Oda et al., 1999](#)) or stable isotope labeling of amino acids in cell culture (SILAC) ([Ong et al., 2002](#); [Zhu et al., 2002](#)), various chemical mass tags (e.g., dimethyl ([Hsu et al., 2003](#)), isobaric tags for relative and absolute quantitation (iTRAQ) ([Ross et al., 2004](#); [Aggarwal et al., 2006](#)) or TMT ([Thompson et al., 2003](#))) or label free strategies. The choice of quantitation strategy for phosphoproteomics depends on various aspects. For example, if the proteins of interest originate from tissues or other biological material, SILAC will not be immediately applicable as this method is optimal for cell cultures. However, in many cases cell lines do not reflect the biology of primary cells and tissues. Metabolic labeling has been applied to whole organisms and subsequent phosphoproteomics studies in various animals such as mouse, rats, *Drosophila melanogaster*, and *Caenorhabditis elegans* ([Fredens et al., 2011](#); [Krijgsveld et al., 2003](#); [Kruger et al., 2008](#); [Wu et al., 2004](#)).

The application of isobaric tags such as iTRAQ and TMT tag requires MS instrumentation capable of stable and efficient analysis of fragment ions in the low mass area. This cannot be done using conventional CID in ion trap instruments due to the mechanism for CID, which does not allow for trapping of fragment masses below 28% of the precursor mass. By applying a relatively novel fragmentation mechanism termed pulsed Q-dissociation (PQD), the analysis of low mass ions in an ion trap become possible, though with a significant decrease in overall identification rate due to the need for multiple micro scans for each peptide to improve quantitation standard deviation ([Bantscheff et al., 2008](#)). HCD fragmentation or CID fragmentation on a QTOF instrument seems to be ideal for quantification using isobaric tags. One significant drawback of isobaric tags, besides that the labeling is performed after proteolysis digestion, is the increase in charge states introduced by these tags ([Thingholm et al., 2010](#)). Recently, we have showed that derivatization of peptides and phosphopeptides with iTRAQ and TMT tags results in a significant increase in charge state and a concomitant reduction in the identification efficiency ([Thingholm et al., 2010](#)). However, the inclusion of ammonia vapor under the electrospray needle was shown to decrease the otherwise increased charge state of isobaric tagged peptides and thereby to improve the identification efficiency of tagged peptides and

phosphopeptides. Furthermore, the ammonia vapor significantly decreases the standard deviation of the isobaric tag analysis as the standard deviation is dependent on the charge state of the analyzed peptides (Larsen MR, unpublished results).

Undersampling, the fact that not all co-eluting peptides will be selected for MSMS, is an issue when performing multiplex comparison of sample conditions and this is most prominent when performing quantification on the MS level (e.g., SILAC and Dimethyl labeling). This is because each peptide is represented by several signals only differing in mass due to the numbers and nature of different isotopes used in the label, reducing the number of unique phosphopeptides selected and fragmented in conventional data dependent analyses.

The isobaric tag approach is compatible with phosphorylation analysis ([Leitner and Lindner, 2009](#); [Gafken and Lampe, 2006](#)) and has been applied to neuronal samples ([Rudrabhatla et al., 2010](#)), fibroblast cells (using ETD) ([Yang et al., 2009](#)), mitochondrial samples (using HCD) ([Boja et al., 2009](#)), and many others (e.g., [Zhang et al., 2005](#); [Wu et al., 2010](#); [Reinl et al., 2009](#)). After quantification of reporter ions, phosphorylation events that depart from those observed in control states (either in absence/presence or in degree) can then be mapped onto pathways using various types of software.

PTM Cross Talk and PTM Coding

PTM cross talk is a relatively recently identified phenomenon which remains fairly loosely described. At a basic level, it can be understood as some form of communication between PTM sites, on a competitive or facilitative basis whereby one site prevents or allows the occurrence of the other, with predictable functional consequences. This phenomenon was first described for the cross talk between O-GlcNAcylation and phosphorylation in regulating signal transduction pathways (e.g., [Wang et al., 2008](#)). This PTM cross talk can be used to provide an extra level of modulation in protein responses by expanding the pool of effectors and providing more points at which to exert control. Cross talk seems to occur with many PTM types (e.g., [Yang and Seto, 2008](#)), but as phosphorylation is the most heavily studied it is well-represented in cross talk literature. For example, as mentioned above phosphorylation has repeatedly been shown to cross talk with O-linked glycosylation ([Wang et al., 2012](#)) to provide close control of Akt signaling in human cells. In addition, protein acetylation has been shown to have a significant influence on phosphorylation in several cellular systems such as the STAT signaling pathway, glucose metabolism, and the molecular response to ischemia and reperfusion ([Parker et al., 2014](#); [Zhang et al., 2012](#); [Wieczorek et al., 2012](#); [Ullmann et al., 2012](#)).

There is also substantial evidence for the role of phosphorylation in more complex PTM patterns that may be used as a form of protein level coding. This recent idea proposes that patterns of PTMs are interpreted as combinatorial coding units by downstream reader proteins, allowing for much more finely regulated control of protein-based processes; see [Figure 3](#) ([Wieczorek et al., 2012](#); [Creixell and Linding, 2012](#)). Evidence for this effect can be seen in situations requiring very tight control of very complex processes, for example, brain

Figure 3 Use of PTMs in a combinatorial coding manner. The figure illustrates an example of PTMs clustering in a region of a protein.

development, wherein both large-scale patterns extending across the whole proteome as well as patterns occurring on individual highly modified proteins can be detected (Edwards *et al.*, 2014a,b).

With the significant increasing interest in PTMs in proteomics and the development of numerous new methods for assessing PTMs in cells, we expect that the field of PTM cross talk will expand dramatically in the coming years and reveal a substantial and yet to be seen complexity in cells.

Challenges in Phosphoproteomics

Today's phosphoproteomic analyses face a multitude of challenges despite the significant progress made in the field. Whereas now it has become relatively easy to isolate thousands of phosphorylated peptides with high specificity, due to the development of highly selective methods for phosphopeptide enrichment, the remaining challenges include accurate phosphopeptide identification, validation, and quantification, and the notorious lack of biological follow-up studies to identify the biological functions of individual phosphorylation sites. This latter point must be addressed if phosphoproteomics is to fulfill its potential with respect to improving our understanding of cell biology.

We, as well as other authors, have recently commented on the identification of phosphorylated peptides based on poor MS/MS signals giving rise to low identification scores in various software programs (White, 2011; Engholm-Keller *et al.*, 2011; Cooper, 2011). Despite recent progress in peptide 'validation' software such as Percolator (Kall *et al.*, 2007) and demands from journals for annotated spectra, we still believe that phosphopeptides in many studies are identified using criteria that are too relaxed and often associated with much higher FDRs (false discovery rates) than reported by the software programs.

An important consideration in phosphopeptide quantification is the interplay between protein abundance and the relative degree of phosphorylation. This site occupancy rate, or the proportion of 'phosphorylatable' sites that are in fact phosphorylated for a particular peptide species, is naturally an important consideration. Estimation of site occupancy for high-throughput approaches is a difficult task given that it requires both detection and accurate measurement of the phosphopeptide and the non-phosphorylated counterpart, and can only strictly be applied to singly phosphorylated

peptides. The biological impact of differential site occupancy is not yet clear but, as it appears to be a tightly regulated phenomenon (Olsen *et al.*, 2010) and given the need for fine control of the complex overlapping pathways, it seems likely to have an important role. Whilst the precise impact of these effects will likely need to be established on a case-by-case basis, a two-stage approach whereby the phosphoproteome and the entire proteome are analyzed concurrently may provide clues to the extent of pathway activation / deactivation in the context of proteome-level changes.

Another increasingly important challenge in phosphoproteomics is the identification and quantification of phosphorylation sites in protein splice variants, which carry the same phosphopeptides. Here, large-scale phosphoproteomics, where the proteins are cleaved into peptides using a specific protease, cannot distinguish the origin of a specific phosphopeptide if it is shared between several variants. If the splice variants participate in different biological pathways or molecular complexes then the quantitative readout will be an average of the splice variants. A perfect example of this was recently given by Chan *et al.* (2010) who examined the phosphorylation of dynamin I isoforms using optimized SDS-PAGE in combination with iTRAQ and LC-MS/MS. They revealed major differential phosphorylation of dynamin I phosphorylation sites in different variants and in different neuronal compartments that would be completely imperceptible to a large-scale phosphoproteomics approach.

Conclusions

As this article has shown, phosphoproteomics is an established yet still developing field. It has advanced enormously from its beginnings in small-scale analysis, but there are challenges that still remain to be addressed. Over the next decade it is our expectation that large-scale phosphorylation analysis will become more and more commonplace as the tools to perform it become more and more advanced, and we will get closer to 100% phosphoproteome coverage from increasingly smaller amounts of material. The suite of bioinformatics tools used to assign biological meaning to this data will also need to advance, though functional roles may only be able to be absolutely described through molecular biological follow-up studies.

Introduction

Enunciated by Crick in 1958, the ‘central dogma of molecular biology’ formulated for the first time how information encoded by molecular alphabets is passed on from genes over messenger RNA to proteins in a defined sequential manner (Crick, 1958). Although this model has since been challenged and nuanced many times, notably by the discovery of RNA viruses, functional noncoding RNA molecules, alternative splicing, posttranslational modifications, and others, this central dogma of molecular biology has opened unprecedented avenues for modern molecular biology. The concept of genes and their products (proteins or RNA) does indubitably play a central role in our understanding of life and has spurred genome sequencing projects for human and model organisms to comprehensively catalog these functional elements. However, it appears that even knowing all functional elements of a cell is insufficient in understanding the bases of cellular life. What is it that we are still missing?

One of the most highly studied human proteins is p53. Its function as a tumor suppressor has been well established but can only be understood in the context of numerous interactions that p53 forms with other proteins and DNA elements (Oliner, 1993). Through binding to promoter regions of various genes involved in growth arrest or apoptosis, p53 can activate their transcription in response to DNA damage. This example illustrates that functional elements, such as proteins, do not work in isolation but interact with each other in a coordinated fashion to carry out cellular functions.

As a key player in regulation of cell growth, p53 itself needs to be tightly regulated. One of the genes activated by p53 is Mdm2, an E3 ubiquitin ligase that mediates ubiquitination of p53 leading to p53 degradation by the proteasome (Fuchs *et al.*, 1998). The interaction of p53 with the promoter of the Mdm2 gene and the interaction between the proteins p53 and Mdm2 form a regulatory mechanism referred to as composite negative feedback loop (Alon, 2007). Together, these two interactions and the ones around them form a system that can lead to different cellular states. Yet despite two decades of intense studies all aspects of this feedback loop are still not perfectly understood reflecting the complexity of the system and of all of its inputs.

Many different systems such as the p53-Mdm2 negative feedback loop, also called network motifs, have been identified and found to form higher order complex regulatory circuits that mediate cellular functions (Alon, 2007). The study of network motifs and their interconnectivity has provided the framework for understanding cells as systems whose scaffold consists of a web of macromolecular interactions, in their entirety called the interactome. Accordingly, interactomes are

essential for approaching the cell as a system and their comprehensive mapping represents the next logical step following genome sequencing (Carvunis *et al.*, 2012). The last decade has seen increasingly successful experimental and computational efforts in providing interactome maps at breadth and depth (Wodak *et al.*, 2013). Though incomplete, such maps, if systematically generated, are representative subsets of the interactome and as such have substantially increased understanding of cellular organization and functions (Vidal *et al.*, 2011). Existing maps contain biophysical or functional interactions. Biophysical interactions comprise direct contacts and co-complex associations of macromolecules whereas functional interactions reflect that two genes or proteins are involved in a common biological process.

The cell coordinates its interactome through various regulatory layers including differential expression and subcellular localization of macromolecules as well as activating and inhibiting mechanisms of macromolecular functions. Current proteome-wide interaction mapping techniques are unable to provide information at such resolution and rather produce sets of possible interactions that then need to be translated into functional relationships and coordinated cellular processes. Key to overcoming these limitations is integration of biophysical with functional interactome maps as well as co-localization and co-expression data to derive functionally meaningful representations of interactome networks (Figure 1; Ge *et al.*, 2003).

Proteins are considered the master connectors and regulators of cellular function given their ability to interact not only with other proteins but also a variety of other types of molecules including DNA, RNA, lipids, glycans, and small molecules. In this article, we provide an overview on different concepts of protein-centric biophysical interactome mapping and will discuss selected studies demonstrating how interactomes modeled as networks and integrated with other systematic functional datasets spurred understanding of cellular systems and how network perturbation can lead to disease.

Methods to Map Interactomes

Methods to map biophysical interactomes can be classified into four main approaches based on their specific aims and outcomes. These are defined as binary mapping, capturing, curation, and prediction (Figure 2).

Binary mapping of interactomes consists of systematic interrogation of pairs of biological molecules for interaction, thereby providing a map of possible binary interactions (Figure 2(a)). This approach relies on *in vitro* or cellular

Figure 1 Interactomes underlie cellular life. Top: Biological functions are mediated through a complex web of interactions between biological molecules. Bottom: Integration of interaction maps from different sources allows deriving more functionally relevant interaction networks representative of different cellular states.

exogenous systems and requires technologies for the high-throughput synthesis of molecular components aimed at interrogating interactions, as well as an efficient and reliable readout to score interactions that do occur.

Capturing approaches act to extract molecular components from a cell together with their associated partners, providing a snapshot of macromolecular assemblies that exist in the interrogated cellular state (Figure 2(b)). Capturing methods rely on techniques for capturing specific molecular components from cell extracts, coupled to analytical methods for the identification of all associated molecules.

Published scientific literature represents a large repository for experimentally derived molecular interactions. The curation approach aims at extracting interaction data from scientific publications to build interactome maps (Figure 2(c)). Given the unstructured text of typical biomedical publications, the curation approach largely relies on manual extraction of interaction information.

Computational approaches provide interactome maps based on prediction, aiming to bypass expensive and time-consuming laboratory experiments. Genomic context, molecular sequences, and secondary and tertiary structure of interacting biomolecules are computationally mined to identify patterns indicative of interactions that can be used to predict new interactions (Figure 2(d)). Molecular dynamics represents one of the computationally most expensive forms of this approach, where simulations search for lowest energy states of a given molecular system, results of which indicate the strength and likelihood of a tested interaction to take place.

Genome and proteome-wide studies need, as much as small-scale experiments, rigorous assessment of both false-positive and false-negative rates as well as a clear understanding of the type of data generated and its properties. Estimation of the size of a given interactome in question allows assessment of the completeness of current interactome

maps and defines future goals. A framework for binary interactome mapping has been proposed, whose principles can be applied to any genome or proteome-scale experiment (Venkatesan *et al.*, 2009). In this framework, the quality and coverage of a dataset is assessed by four parameters: screening completeness (the fraction of the full space screened), assay sensitivity (fraction of interactions detectable by the assay), sampling sensitivity (fraction of detectable interactions detected in one screen), and precision (fraction of identified interactions that are true positives). Core to this framework is accounting for the space screened, the use of a positive and random reference set (PRS and RRS) of interactions serving as gold standard and negative control sets, respectively, and validation of interactions with orthogonal assays (Venkatesan *et al.*, 2009; Yu *et al.*, 2008).

Different implementations of the four interactome mapping approaches have been developed to accommodate characteristics specific to the various groups of biological molecules (proteins, DNA, RNA, lipids, glycans, and small molecules) with which proteins interact. In the following sections, we will provide an overview on widely used techniques for protein-centric interactome mapping and discuss biases, quality, and completeness issues of generated maps.

Mapping Protein–Protein Interactions

Protein–protein interactions (PPIs) constitute a highly investigated type of biomolecular interactions. Several orthogonal proteome-scalable methodologies have been developed to interrogate pairs of proteins for binary interactions.

Classical yeast two-hybrid (Y2H) (Fields and Song, 1989) is based on the functional reconstitution of the Gal4 transcription factor (TF), whose DNA-binding domain and activation domain are fused to bait and prey proteins, respectively. These fusion constructs are expressed in yeast cells, and bait

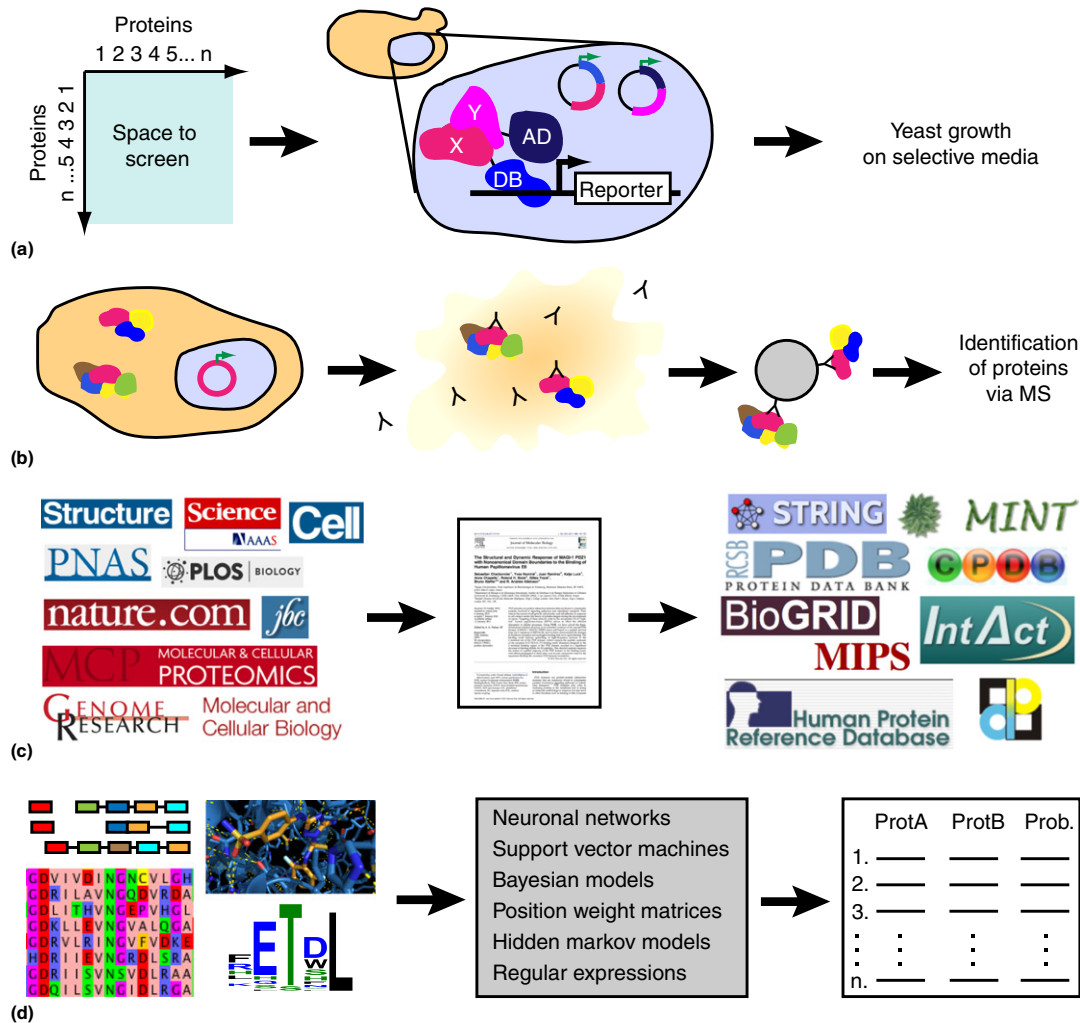

Figure 2 Four approaches to map interactomes. Examples have been drawn from PPI mapping. (a) Binary mapping (Y2H). Pairs of bait and prey from a defined search space are systematically expressed in cells as fusion constructs with reporter protein fragments. Upon interaction of bait and prey, the two fragments of the reporter protein are brought in close proximity reconstituting reporter protein function. Resulting signals indicate a direct and binary interaction between bait and prey. (b) Capturing (AP-MS). A bait, usually expressed from a plasmid, forms complexes with its interaction partners, the preys. After cell lysis baits together with preys can be captured and purified using specific antibodies or coated beads against the bait or against a fused epitope tag. Bait and prey in purified complexes are identified by MS. (c) Curation. Published literature is manually curated to extract information on protein-mediated interactions, which are imported and maintained in public databases. (d) Prediction. Conservation of sequence, patterns of recognition, genetic context, functional relationships, co-expression patterns, structural data, and many more types of data can be mined to predict protein-mediated interactions. Information provided from these resources is used as input into various learning algorithms, which after training, produce for a given pair of proteins a probability or predicted binding affinity indicating the likeliness or strength of a potential interaction between those.

and prey proteins that interact reconstitute a functional TF that activates a reporter gene used for readout. In classical Y2H, bait and prey need to interact within the nucleus and non-yeast bait and prey proteins need to remain functional in a foreign cellular environment, representing limitations of this methodology. Advantages of this well-established approach are the independence from sophisticated equipment and low costs, enabling its scalability.

Protein complementation assays (PCA) using fragments of ubiquitin (Johnsson and Varshavsky, 1994), dihydrofolate reductase, an essential metabolic enzyme, and fluorescent or luminescent proteins have been developed to detect binary interactions in yeast and mammalian cells. Signal readouts can

be cellular growth or emitted light, depending on the reporter protein implemented. Unlike Y2H, PCA is not restricted to nuclear localization of bait and prey, but some implementations seem to indicate proximity of bait and prey rather than a direct interaction (Stylen *et al.*, 2012).

Mammalian protein-protein interaction trap (MAPPIT) and luminescence-based mammalian interactome mapping (LUMIER) are binary mapping assays that function in mammalian cells. In MAPPIT, bait and prey are fused to members of the JAK/STAT signaling pathway that upon interaction at the inner surface of the plasma membrane mediate activation of the TF signal transducer and activator of transcription 3 (STAT3), which activates a reporter gene

(Eyckerman *et al.*, 2001). LUMIER is a pulldown-based assay where preys tagged with the immunoaffinity FLAG peptide epitope are pulled down from cell extracts and interactions with bait proteins fused to luciferase are quantified by measuring luminescence signal intensity (Barrios-Rodiles *et al.*, 2005).

Nucleic acid programmable protein array (NAPPA) is an *in vitro* method where FLAG-tagged bait and prey proteins are synthesized in an *in vitro* transcription–translation system. Upon synthesis bait proteins are captured and non-covalently attached to a membrane. The co-synthesized interacting prey can be detected via its FLAG immunoaffinity tag (Ramachandran *et al.*, 2004).

None of these assays can formally exclude the possibility that endogenous yeast or mammalian proteins mediate the observed interactions between bait and prey. Interaction datasets derived from binary mapping methods show negligible bias with respect to endogenous protein expression levels, but the physiological context under which detected interactions may occur remains uncertain. Fundamental variations in methodological design define different chemical environments under which pairs of proteins are tested for interaction leading to different subsets of interactions detected. Combining interaction maps derived from different methods thus increases overall coverage (Braun *et al.*, 2009).

Proteome-wide binary interactome mapping, mostly done with Y2H, has been achieved for several bacterial species, *Saccharomyces cerevisiae* (yeast), *Caenorhabditis elegans* (worm), *Drosophila melanogaster* (fly), *Arabidopsis thaliana* (plant model organism), and *Homo sapiens* (human) (reviewed in Ryan *et al.*, 2013; Carvunis *et al.*, 2012; Vidal *et al.*, 2011; Wodak *et al.*, 2013). The number of interactions identified in these screens ranges from several hundred for the earliest maps to ~14 000 interactions for human involving ~4300 proteins (Rolland *et al.*, 2014). The yeast protein–protein interactome has been mapped at proteome scale several times, yet the union of three high-quality Y2H-derived binary interactome maps from yeast (only) represents about 15% (2930 PPIs) of its total estimated size ($\sim 18\,000 \pm 4500$ PPIs) (Yu *et al.*, 2008).

Affinity purification coupled to mass spectrometry (AP-MS) represents the most widely used implementation of capturing methods for PPIs. AP-MS captures protein complexes from cells expressing bait proteins either directly or via fused immunoaffinity tags. After cell lysis, baits are purified together with associated prey proteins, which are subsequently identified by MS. Comprehensive mapping by AP-MS of protein complexes of *E. coli*, yeast, and fly have all been reported (reviewed in Ryan *et al.*, 2013; Carvunis *et al.*, 2012; Vidal *et al.*, 2011; Wodak *et al.*, 2013). Each report identified up to 600 distinct protein complexes and up to 5000 distinct proteins in total. The union of three tandem affinity purification–mass spectrometry (TAP-MS) maps of yeast PPIs represents about 40% of the yeast interactome (Collins *et al.*, 2007). Mammalian protein complexes derived by AP-MS have been reported at the scale of individual biological processes but mapping at proteome scale has faced difficulties expressing tagged bait proteins at high-throughput in mammalian cells (Gingras *et al.*, 2005). However, mammalian proteome-scale datasets are now emerging in public repositories (Huttlin *et al.*, 2014,

pre-release on thebiogrid.org). Many proteins function as part of multi-subunit complexes, and AP-MS data provide insights into protein complex composition at a given cellular state. AP-MS lacks the resolution to determine, if all prey proteins pulled out by a bait protein occur in the same or in different complexes, and to dissect which proteins directly bind each other within a complex. AP-MS data show biases toward higher affinity interactions and contrary to binary methods, also toward more highly expressed proteins (Wodak *et al.*, 2013).

Another recent approach for proteome-scale protein complex capture involves direct chromatographic separation of cell extracts. Proteins co-migrating together in the same biochemical fractions are identified via MS and are presumed to be part of the same protein complex (Havugimana *et al.*, 2012).

Given the different properties of binary PPIs versus protein complex associations, it is important to discriminate between interactomic data derived from binary and capturing techniques (Yu *et al.*, 2008). Overlaps of interactome maps derived from Y2H and AP-MS or even between interactome maps derived from the same method seem small, but when controlled for space and assay sensitivities, are highly significant (Yu *et al.*, 2008; Wodak *et al.*, 2013). The complementarity of TAP-MS and Y2H protein interaction datasets has been exploited to dissect potential binding interfaces between pairs of proteins within protein complexes in *E. coli* (Rajagopala *et al.*, 2014).

Due to experimental limitations, most PPI mapping efforts necessarily disregard the existence of alternatively spliced isoforms of a gene and splice variants of the same genes are generally not distinguished in current PPI maps. Alternative splicing can selectively remove or add binding sites to isoforms, suggesting major differences in interaction partners may exist between isoforms from the same gene (Ellis *et al.*, 2012).

An important resource of PPI information comes from literature curation. Numerous public databases store curated PPIs, including direct and indirect, binary and complex, and biophysical and functional relationships (Orchard, 2012). Recent initiatives aimed at facilitating the time-consuming and ambiguous task of literature curation, have defined guidelines for the requisite information for a molecular interaction to be reported in a publication (MIMIX (minimum information about a molecular interaction experiment); Orchard *et al.*, 2007), standardized the file format in which interactions are curated (HUPO-PSI-MI format (Human Proteome Organization Proteomics Standards Initiative Molecular Interaction format); Orchard and Hermjakob, 2008, MITAB format (molecular interaction tabular format); Kerrien *et al.*, 2007), and unified access to curated interaction data (Aranda *et al.*, 2011).

Numerous strategies have been developed to predict protein interactions, yet the performance of those applicable at proteome scale seems still limited (Rolland *et al.*, 2014). To infer PPIs, predictive methods incorporate phylogenetic information captured in sequence alignments (e.g., used to infer interologs, conserved interactions across species), genetic neighborhood information, sequence composition, and patterns or motifs in primary sequences, three-dimensional (3D) structural information and molecular dynamics (Tuncbag *et al.*, 2011; Franceschini *et al.*, 2013). Most predictive methods only concentrate on a particular type of protein interaction,

those mediated by short linear motifs (Weatheritt *et al.*, 2012) or those between globular domain interfaces (Mosca *et al.*, 2014). A recent proteome-wide domain–domain interaction prediction utilized the growing repertoire of 3D structures of interacting proteins (Zhang *et al.*, 2012). Structural homology modeling allowed assignment of a structural template to about two-thirds of human proteins without an existing structure but with at least one globular domain. The resulting homology models were then used to search for compatible interaction interfaces at a proteome-wide scale.

A comparison of four proteome-scale maps of human PPIs each derived from a different mapping approach: binary (Rolland *et al.*, 2014), capturing (Havugimana *et al.*, 2012), curation (Rolland *et al.*, 2014), and prediction (Zhang *et al.*, 2012) revealed interesting insights into biases displayed by each of these maps with respect to a variety of gene properties investigated. Notably, the literature and capturing map were significantly biased toward highly studied genes and genes of high-expression levels. The prediction map was depleted of proteins without structured domains and also suffered from inspection biases. All four maps performed poorly in identifying interactions involving membrane proteins. Out of these four maps, the binary map performed best with respect to homogeneously covering the human PPI space. Nevertheless, each map adds unique and valuable information to the human protein–protein interactome and contributes to increasing its coverage.

Mapping Protein–DNA Interactions

Two methods currently dominate the field of binary protein–DNA interaction (PDI) mapping at proteome-scale, protein-binding microarrays (PBM) and yeast one-hybrid (Y1H). In PBM double-stranded DNA is attached on an array and probed for interaction with purified proteins, TFs in particular. Current microarrays can contain every possible sequence variant of a 10-mer oligonucleotide, enabling derivation of DNA-binding specificities for a given TF. PBMs have been applied to homeodomain-containing TFs of mouse and to most yeast TFs (Dey *et al.*, 2012). The results characterized *in vitro* DNA-binding specificity ranges as well as mechanisms of DNA sequence recognition by proteins. PBM data can be transformed into DNA-binding profiles that are used to query genome sequences for prediction of TF-specific target sites and for generation of protein–DNA interactome maps. PBM technologies are protein-centric, i.e., the DNA-binding capabilities of a given protein are interrogated.

The principles of Y1H, another binary gene-centric assay, are similar to Y2H in that the yeast cells are used to interrogate exogenous bait and prey molecules for binary interactions. The DNA bait sequence, usually a presumptive *in vivo* promoter region, is placed upstream of a reporter gene. Protein preys fused to an activation domain can activate the reporter gene upon binding the DNA bait. In contrast to PBMs, Y1H data can directly be used to generate interactome maps. Y1H can screen large DNA fragments, entire promoter sequences hundreds or thousands of nucleotides long, as compared to microarray technologies which are limited to small oligonucleotides (Walhout, 2011). Overall sensitivities of Y1H have been

estimated to lie between 33 and 77%, depending on the actual form of the assay used, with a sampling sensitivity of a highly automated Y1H assay as high as 89% (Reece-Hoyes *et al.*, 2011). Estimation of false-positive rates is hampered by the difficulties in generating negative reference sets. Y1H has been applied at biological process and proteome scale to worm, *A. thaliana*, and to human, involving up to 1000 protein preys (70% of the predicted human TFs) and up to 200 DNA baits, generating interactome maps containing several hundred PDIs (Gaudinier *et al.*, 2011; Reece-Hoyes *et al.*, 2011).

Chromatin immunoprecipitation (ChIP) is a protein-centric capturing technique that identifies PDIs *in vivo*. The protein baits are crosslinked to the DNA they bind via a chemical cross-linking agent, usually formaldehyde, followed by a fragmentation of the DNA and immunoprecipitation using antibodies specific to the protein bait. The immunoprecipitated DNA molecules can be identified via either microarrays (ChIP-chip) or sequencing (ChIP-seq). ChIP is the method of choice when *in vivo* DNA-binding sites need to be identified for selected TF (Walhout, 2011). ChIP has been applied at proteome scale to map genomic binding regions for hundreds of yeast and human TFs (Dey *et al.*, 2012). ChIP investigations across five human cell lines as part of the ENCODE project generated cell-type specific PDI maps (ENCODE Project Consortium *et al.*, 2012). The power of ChIP is limited by its requirement for antibodies against specific TFs, restricting ENCODE data to fewer than 10% of the predicted human TFs. Weakly or non-expressed endogenous TFs can only be mapped with ChIP upon cellular transformation with plasmids, which express a TF of interest. Y1H is more amenable than ChIP to proteome-scale mapping because of its independence of antibodies and endogenous expression of TFs (Walhout, 2011). Due to the cross-linking, the washing steps in ChIP can be stronger than in AP-MS, removing adventitiously associated proteins. Protein–protein cross-linking can occur, albeit at a much lower rate than protein–DNA cross-linking, leading to possible isolation of protein–DNA complexes where TFs are associated with DNA elements via a bridging protein. Bridging may also occur in Y1H to mediate observed interactions between DNA bait and protein prey. Contrary to ChIP, Y1H and PBM generally miss interactions for TFs that function as heterodimeric complexes or which require cofactors.

Unlike curated PPI literature datasets, which also include information from small-scale studies, curated PDI datasets are mostly derived from proteome-scale or structural studies (Dey *et al.*, 2012).

Two main types of data are used to infer PDIs, DNA-binding profiles such as those derived from PBM studies (Weirauch *et al.*, 2013), or gene expression profiles based on co-expression of genes over a range of different cellular conditions (Margolin *et al.*, 2006). Integration of gene expression data with PPI data, DNA-binding profiles, and text-mining results can substantially increase the functional relevance of predicted PDI maps (Olsen *et al.*, 2014).

Mapping Protein–RNA Interactions

RNAcompete is an *in vitro* method that incorporates aspects of both capturing and binary interaction technologies. A protein of interest is incubated with a large pool of RNAs, each up to

41 nucleotides long, covering all possible sequence combinations of 9 nucleotides. After incubation, the protein gets extracted with an affinity tag and bound RNAs are identified on microarrays. This method has been applied to derive RNA-binding profiles for more than 200 RNA-binding domains (RBD) from 20 different eukaryotic species (Ray *et al.*, 2013). Binding profiles have consequently been used to predict binding sites of these RBDs in 5' and 3' untranslated regions as well as in alternative exons and flanking introns of messenger RNA (mRNAs). Integration with mRNA expression and alternative splicing data-enabled prediction of functions for these RBDs.

An approach similar to ChIP has been developed and applied at proteome scale to capture protein–RNA interactions (PRIs), termed cross-linking and immunoprecipitation (CLIP). Cross-linking between protein and bound RNA molecules is achieved via ultraviolet (UV) light at specific wave lengths. After immunoprecipitation, crosslinked RNA molecules can either be reverse transcribed, amplified, and sequenced (CLIP-seq) or identified using microarrays (CLIP-chip). A refinement of the cross-linking technique is PAR-CLIP (photoactivatable ribonucleoside CLIP), where cells are grown on media containing 4-thiouridine (4SU) instead of uracil to incorporate 4SU into RNA molecules. Upon reverse transcription of captured RNA molecules crosslinked 4SU introduces a thymine to cytosine mutation allowing precise determination of protein-binding sites. CLIP and its variations have been applied transcriptome-wide to study binding of selected RNA-binding proteins to mRNAs and microRNAs (miRNAs) (reviewed in Konig *et al.*, 2011). CLIP has also been successfully combined with MS to identify hundreds of novel mRNA-binding proteins via capturing of polyadenylated RNAs with oligo-thymine beads (reviewed in Ascano *et al.*, 2013). Given accumulating evidence indicating major roles in cellular regulation for noncoding RNAs, there is a clear need to extend PRI mapping efforts from mRNA toward noncoding RNAs.

A few efforts have been made toward PRI curation from the literature with a focus on PRI curation and analysis from published structures in the Protein Data Bank (PDB) (Fujimori *et al.*, 2012).

RNA-binding profiles for proteins can be derived from methods such as RNAcompete and used to predict PRIs. Other approaches to PRI prediction are low-throughput using protein structural and primary sequence information (Puton *et al.*, 2012).

Mapping Protein–Lipid and Protein–Glycan Interactions

There is no genetic code and unique synthesis machinery for lipids and glycans as exists for DNA, RNA, and protein synthesis. The lipidome, as is the glycome, is synthesized by a diverse set of enzymes using different educts as starting material. This complexity in compound synthesis explains why methods to study interactions of these molecules with proteins at scales similar to those for proteins and nucleic acids are still lacking.

Lipids are anchored in cellular membrane structures, making the capturing of PLIs from living cells at proteome scale intractable. Detection of PLIs mostly relies on binary mapping technologies using protein or lipid arrays where

bound targets are identified using either tags or MS. A promising attempt toward systematic PLI mapping used lipid arrays (Gallego *et al.*, 2010) to assay binding of 56 lipids to 172 yeast proteins predicted to be involved in lipid metabolism or containing lipid-binding domains. In total 530 protein–lipid interactions (PLIs) were detected, including novel lipid-binding domains. At lower scale, lipid-binding potentials of specific classes of domains (e.g., PDZ domains) have been studied across a variety of lipids by surface plasmon resonance (SPR) (Chen *et al.*, 2012). The resulting quantitative binding information together with structural data has been used to predict domain–lipid interactions.

These binary approaches used isolated lipids attached to arrays or chips. Under physiological conditions lipids occur in membranous lipid layers, the actual interaction surface encountered by lipid-binding proteins. To mimic these conditions, a strategy has been developed to attach entire liposomes of defined composition onto arrays and to probe them with purified proteins for interaction using fluorescence microscopy for readout (Saliba *et al.*, 2014).

PGI mapping at large scale is even more challenging than PLI mapping. The complex branching structure of glycans, based on highly similar monosaccharide building blocks, hinders unambiguous identification by MS (Rakus and Mahal, 2011). A functional glycomics consortium generated a publicly available glycan microarray containing more than 500 probes to assay binding specificities of glycan-binding proteins (Smith *et al.*, 2010).

Mapping Protein–Small Molecule Interactions

A large fraction of protein–small molecule interactions (PSMIs) are enzymatic (biochemical), characterized by chemical modification of the small molecule via its interacting protein, the enzyme. Enzymatic interactions are short-lived, as immediately upon modification the resulting product dissociates from the protein. Interaction mapping approaches thus need to be different for PSMIs that are enzymatic versus those that are not. Because of their instability, PSMIs that are enzymatic can best be indirectly measured by solution-based *in vitro* enzyme assays where appearance or loss of metabolites is detected. The throughput of such approaches is limited. Interactome maps of enzymatic PSMIs have mainly been built from literature-curated datasets, which for this type of interaction can reach high coverage (Kanehisa *et al.*, 2014).

Nonenzymatic PSMIs, such as allosteric, inhibitory, cofactor, or ligand interactions, are generally longer-lasting depending on the actual reaction constants. These interactions are measurable by binary mapping and capturing methods whose applications have been predominantly drug development. The aims are to either identify for a given protein (or protein class) a potent inhibitor (drug) of the activity of that protein, or alternatively to identify all protein targets of a given small molecule (drug) to understand mechanism of action and side effects referred to as protein- and drug-centric interaction mapping, respectively. A combination of computational and experimental binary testing has been used to address protein-centric interaction mapping. Via computational docking the potential scaffold or class of small molecules with biological activity toward the given protein or class of proteins

can be determined. In consecutive experimental screens, derivatives of the identified small molecule class are screened versus targets to identify the high-affinity binders. The most frequently screened drug target classes are G-protein coupled receptors, nuclear receptors, ion channels, kinases, phosphatases, and proteases. Experimental screens can be carried out using arrays and MS (Zinn *et al.*, 2012), or methods of lower throughput (nuclear magnetic resonance and SPR) which can return quantitative binding information.

Capturing methods, also referred to as chemoproteomic approaches, have powerfully addressed drug-centric interaction mapping. A given drug is immobilized on a matrix and interrogated with a cell extract. After incubation and extensive washing, bound proteins can be eluted and identified by MS (Colinge *et al.*, 2012).

An indirect mapping approach has been proposed to map allosteric interactions regulating the switch from gluconeogenesis to glycolysis in *E. coli* (Link *et al.*, 2013). Changes in metabolite concentrations upon frequent switches between pyruvate and glucose or fructose in bacterial media have been determined and fit to models of metabolic pathways. Some 126 predicted allosteric interactions were successfully validated experimentally.

The Role of Genome Sequencing for Interactome Mapping

Sequenced genomes are essential for systematic and proteome-wide interactome mapping by binary or capturing approaches. Assay design for both approaches depends on preexisting knowledge of the molecular components that constitute the interactome in question. The completeness of such lists of molecular components including protein, DNA, and RNA, entirely relies on the availability of sequenced genomes (Hood and Rowen, 2013). Recent improvements in mass spectrometry and DNA sequencing technologies have enabled and accelerated proteome-scale interactome mapping with binary and capturing approaches. DNA or RNA reads resulting from sequencing of preys need to be aligned to a reference genome for identifying the corresponding genes. MS spectra of peptides need to be compared to theoretical spectra derived from all possible peptides of a reference proteome to identify the corresponding proteins. Immunoaffinity tags can only be fused to known baits and only for known baits can specific antibodies be derived. Binary mapping technologies depend on open reading frame (ORF) collections of known genes for the synthesis of proteins. With the availability of genome sequences at increasing depth and accuracy, along with increasing power and throughput of interaction mapping approaches, a human reference interactome project in analogy to the human reference genome project is becoming a possibility (Vidal and Fields, 2014).

Applications of Interactome Maps

Protein interactome maps are readily represented as networks, where biomolecules are the nodes of the network and the interactions between them are the links or edges (Barabási and Oltvai, 2004; Figure 3). Gene regulatory networks can be built

Figure 3 Network biology. The small network illustrates some of the properties of protein-mediated interaction networks. Nodes represent proteins and their partners, edges interactions between them. This undirected network is scale-free as indicated by the inset histogram of degree distribution, meaning that many nodes are only engaged in one or two interactions whereas very few nodes are hubs (e.g., node 12). Subsets of nodes can be highly connected forming clusters indicating function in a common biological process (blue circle).

from TFs mapped to DNA-binding sites, linking the genes encoding for the TFs with the genes they positively or negatively regulate. In metabolic networks, nodes are metabolites and edges between them represent reactions catalyzed by known enzymes. PPI networks are mostly undirected, where the direction of interaction cannot be stipulated. Gene regulatory and metabolic networks represent directed networks (Vidal *et al.*, 2011). Once in network format, the powerful tools and analyses of graph theory can be applied to assess structural properties of cellular interaction networks and to derive principles of cellular organization (Barabási and Oltvai, 2004).

Interaction Network Structure Reflects Biological Function

The most elementary characteristic of a node is its degree. In nearly all interactome networks the degree distribution follows a power law (Figure 3) and such networks are known as scale-free networks, meaning that most nodes have a low degree whereas a small number of nodes have an unusually high degree compared to the mean degree; such high-degree nodes are called hubs (Barabási and Oltvai, 2004). This organization contrasts to random networks, which follow the Poisson or Gaussian degree distribution, where the degree of most nodes is close to the mean node degree. Scale-free networks display robustness, showing insensitivity toward random attacks, since the random removal of a node is more likely to remove a low-degree node than a hub, but extreme sensitivity to attacks

directed at hubs, since hubs are so highly connected (Albert *et al.*, 2000).

A node with high degree is better connected in the network and is likely to be part of many shortest paths between other nodes. A high-degree node therefore plays a more important role in maintaining the network structure and information flow than nodes of low degree. A logical expectation is that hubs in a PPI network are more likely to correspond to essential proteins (Jeong *et al.*, 2001), however, the underlying biological reasons for such relationship and its overall existence have long been debated (Zotenko *et al.*, 2008). Clear correlations between degree and essentiality have been observed using PPI networks derived from literature curation contrary to using systematically generated networks (Zotenko *et al.*, 2008; Yu *et al.*, 2008). Networks obtained from curation are heavily biased toward interactions involving proteins perceived as most biologically important and essential (Rolland *et al.*, 2014). The lower degree of nonessential proteins may simply result from those proteins being understudied. Using a systematic binary map of yeast PPIs, it has been shown that degree in an interactome network rather correlates with genetic pleiotropy, the number of phenotypes observed as a consequence of gene removal, than essentiality (Yu *et al.*, 2008).

Overlaying transcriptome profiles with a binary interaction network enabled classification of two types of highly connected hub proteins – party hubs and date hubs. Party hubs are co-expressed with most of their interacting partners; while date hubs connect to different partners at different times or contexts (Han *et al.*, 2004). Structural differences between date and party hubs reflect their different network properties. With date hubs different interacting partners may utilize the same surface of interaction at different times, whereas party hubs tend to contain fewer disordered regions and to display more interaction interfaces on their surfaces, as would be expected for proteins with many simultaneous interacting partners (Kim *et al.*, 2008). Integrating date and party hubs with protein subcellular localization, functional, and genetic interaction data identified interaction partners of party hubs as being more co-localized, more often part of the same functional module, and less correlated with genetic interaction data than date hubs (Han *et al.*, 2004).

Molecular interaction networks contain cliques or communities, which are clusters of nodes that are highly connected to each other (Figure 3). Identified clusters of nodes in molecular interaction networks have been termed topological modules. Modularity is a central hallmark of cellular organization. Biomolecules within a topological module usually participate together in a specific cellular function (e.g., translation) often by forming a specific complex (e.g., the ribosome) (Barabási and Oltvai, 2004). Topological modules often correspond to functional modules. Perturbation of any of the molecules forming a functional module can lead to closely related phenotypes or diseases (Goh *et al.*, 2007). In PPI networks, all proteins that upon disruption lead to the same disease can be grouped into disease modules that generally, but not always, overlap with functional and topological modules (Barabási *et al.*, 2011; Vidal *et al.*, 2011).

In summary, the connectivity structure of interaction networks, that is, the topology, leads to definition of biological processes through delineation of modules, and can inform

upon how biological processes are disrupted in disease and how disease therapeutics can be designed and evaluated, as examples in the next section relate.

Interactome Maps Contribute to Our Understanding of Cellular Organization and Human Disease

Integration of data from multiple sources acts to increase data reliability and provides complementary functional evidences, which can help to develop biological hypotheses, both for follow up on individually selected interactions as well as on emerging systems properties (Figure 1; Ge *et al.*, 2003). A first attempt to combine large-scale datasets of different kinds uncovered significant correlations between gene expression and protein interaction data, in that protein interaction clusters tended to significantly overlap with clusters of co-expressed genes (Ge *et al.*, 2001).

Interactome maps and cell communication

Interactome mapping of particular functional modules or biological pathways has identified new regulators and effectors of these modules or pathways, unraveling their molecular complexity and redundancy. Pathway specific interactome mapping has been carried out for proliferative pathways often deregulated in multiple diseases: PI3K-mTOR pathway (Pilot-Storck *et al.*, 2010), the MAPK pathway (Bandyopadhyay *et al.*, 2010), the TGF β pathway (Tewari *et al.*, 2004; Barrios-Rodiles *et al.*, 2005), and the Hippo pathway (Kwon *et al.*, 2013). The PI3K-mTOR Y2H interactome map (Pilot-Storck *et al.*, 2010) identified 67 new interactions between 33 components of the pathway of which several were analyzed for their role in mTOR signaling. Systematic TGF β interactome mapping and integration of the resulting interaction network with genetic perturbation data led to the identification of nine pathway modifiers within a network of 71 interactions among 59 pathway components (Tewari *et al.*, 2004). PPI maps centered on molecular machines have been generated for the yeast mediator complex (Guglielmi *et al.*, 2004) and the human spliceosome (Hegele *et al.*, 2012).

Integration of protein interactome data with phenotypic and expression data furthered understanding of the DNA damage response (Boulton *et al.*, 2002) and of early embryogenesis in worm (Gunsalus *et al.*, 2005). Overlaying PPI data, gene expression data, genetic interaction data, and phenotypic data predicted positive and negative regulators of signaling pathways and protein complexes in fly (Vinayagam *et al.*, 2014).

Interactome maps and human disease

Next generation sequencing technologies produce a wealth of genomics data from genome-wide association studies (GWAS) or cancer genome sequencing initiatives, which catalog mutations implicated in the development of disease. Given the speed and low cost of sequencing, the functional characterization of mutations lags a long way behind their identification. Mutations often cause cellular network perturbations eventually leading to a disease state. Systematically mapping cellular interaction networks and profiling perturbations of interactions caused by mutant alleles (edgotyping) may help

Figure 4 Understanding cellular organization and disease through interactome networks. Perturbations of protein function, either genetic or nongenetic, can disrupt interactome network organization. Deciphering those network disruptions can offer explanations of the phenotypic outcomes that are observed.

enlighten genotype-to-phenotype relationships between mutations and diseases (Figure 4; Sahni *et al.*, 2013). Furthermore, it has been shown that interaction mapping can help discriminating disease-causing from non-disease relevant mutations where the former tend to more often lead to network perturbations (Rolland *et al.*, 2014).

PPI network-based approaches have been applied to human disease, in particular to cancer. Integration of PPI data with gene expression data identified subnetworks predictive of metastasis in breast cancer (Chuang *et al.*, 2007). An analogous integrative approach identified novel breast cancer susceptibility and modifier genes (Pujana *et al.*, 2007). Network analysis of a proteome-wide systematically derived binary PPI dataset revealed that ‘cancer genes’ tend to have a higher degree and to be more highly connected to each other than random sets of genes. These findings have been consequently used to prioritize cancer-candidate genes by identifying interactions in existing PPI networks between genes in loci derived from cancer GWAS and known cancer genes (Rolland *et al.*, 2014). The generation of disease centric interactome maps for human inherited ataxias (Kahle *et al.*, 2011) and autism spectrum disorders (Corominas *et al.*, 2014), has provided fresh insights into disease mechanisms, such as unexpectedly high connectivity between disparate disease proteins for ataxia and autism, suggesting that convergent molecular pathways underlie phenotypes in distinct syndromes.

Interactome maps of host–pathogen interactions

Pathogens target key host proteins in an attempt to control and subvert intracellular pathways to facilitate their survival in host cells (Davey *et al.*, 2011). Systematic mapping of host–pathogen PPIs identifies points of perturbation in host networks and delineates strategies adopted by different pathogens for host invasion (Figure 4).

Systematic mapping of virus–host PPI maps or ‘virhostome’ maps has been undertaken for many specific viruses such as influenza virus, Epstein–Barr virus, hepatitis C virus, herpesviruses, human immunodeficiency virus, or human T-lymphotropic virus (De Chassey *et al.*, 2014). In another proteome-scale effort, 123 viral ORFs derived from several DNA tumor viruses have been systematically mapped for interactions with human proteins using Y2H and TAP-MS (Rozenblatt-Rosen *et al.*, 2012). Integration of this interaction dataset with gene expression data, functional annotations, and TF-binding profiles implicated many members of the Notch signaling pathway in viral pathogenesis and tumorigenesis. Identified human interaction partners of oncogenic viral proteins were enriched for proteins involved in cancer and more specifically for tumor suppressors, pointing to the ability of this systematic approach to aid identification of driver genes in cancer (Rozenblatt-Rosen *et al.*, 2012).

Not only viral but also bacterial pathogens can be investigated by focused interactome mapping. Bacterial virulence factors in the *Mycobacterium tuberculosis* secretome were screened by Y2H for interactions with host proteins (Mehra *et al.*, 2013). This revealed an interaction between the bacterial protein EsxH and the human hepatocyte growth factor-regulated tyrosine kinase substrate (Hgs/Hrs), a component of the endosomal sorting complex, which was shown to play a role in tuberculosis pathogenesis.

Interactome maps, drugs, and drug targets

Mapping of disease-centered interactomes can help identify new proteins causative of disease, and at the same time present potential targets for the development of novel therapies (Vidal *et al.*, 2011). A noteworthy approach to rational drug design integrated metabolic networks with gene expression data derived from cancer samples to generate a model of cancer metabolism that successfully uncovered known metabolic

drug targets in cancer and predicted new candidate drug targets (Folger *et al.*, 2011).

The targets, mechanism of action, and metabolism of many approved and widely applied drugs are still unknown, contributing to poor understanding of drug side effects. Because cells function as a system, the perturbation of one or several drug targets is likely to have system-wide effects and to lead to extensive network remodeling. Drug–protein interaction and PPI mapping combined with measurements of gene expression changes metabolic and phenotypic profiling and integration with patient clinical data and side effect records has been frequently employed to close these gaps in knowledge and to aid in the development of new drugs (Iskar *et al.*, 2012). Chemoproteomic approaches allow identification of many targets of a drug. Searching for functional enrichments within sets of targets using functional annotations of genes can highlight the biological processes or pathways potentially affected by a given drug. Expanding the small set of known drug targets by selected interaction partners derived from PPI networks can increase the performance of such enrichment analyses. Only when enriching the set of targets from the cancer drug bosutinib with neighbors derived from PPI networks was its association with the immune system pathway revealed (Colinge *et al.*, 2012).

Mapping the genes likely affected in a disease via genotyping and the proteins likely to be perturbed by a drug using molecular interaction data, followed by a comparison of the two profiles, allows the efficiency of a drug to be estimated and the identification of potential side effects (Colinge *et al.*, 2012). Comparing drug target profiles with several disease gene profiles can reveal potential for drug repurposing. Such an approach was used to successfully predict the effectiveness of dasatinib to treat lung cancer (Colinge *et al.*, 2012). Combining interactome data with patient specific disease gene profiles may be applied to allow adjustments to drug administration based on a patient's genetic background, the aim of personalized medicine.

Pharmacological networks that illustrate the relationships between known drugs, their targets and disease-causing genes have been generated by integration of drug–protein interaction and PPI data with gene expression and genetic disease annotations (Yildirim *et al.*, 2007). Drugs tend to have multiple targets and proteins are targeted by multiple drugs leading to a highly connected network. Drug targets tend to fall in between peripheral poorly connected nodes of a network and hubs (likely essential proteins), providing a statistical network approach to prioritization of new potential drug targets (Yildirim *et al.*, 2007).

Inhibiting one target has often been ineffective in treating complex diseases such as cancer, autism, or asthma, all arising from perturbation of multifaceted biological processes (Zimmermann *et al.*, 2007). Functional redundancies confer robustness to cellular networks but also result in drug resistances where drug perturbations can be compensated for or buffered by redundant cellular regulatory mechanisms (Hanahan and Weinberg, 2011). Such limitations can be overcome by targeting complex diseases with drug combination therapies (Zimmermann *et al.*, 2007), already applied to cancer (Csermely *et al.*, 2005). Given the complexity of cellular systems and quantity of available drugs, simple systematic

screening for potential drug combinations is unfeasible. Integration of drug-relevant orthogonal datasets including interactome maps has been successfully employed to delve into the mechanism of action of drug combination therapies, to propose new potential drug combinations and to narrow down the search space (Barabási *et al.*, 2011).

Perspectives

Substantial progress has been achieved toward mapping interactomes of different types of interactions and for different species. Integration of these data with orthogonal systematically derived datasets has advanced understanding of how cellular systems are organized and regulated, and has enabled a systems view on disease mechanisms. Current interactome maps suffer from incompleteness and biases that restrict potential downstream analyses and the set of approachable biological questions. Future efforts in interactome mapping will have to overcome these limitations.

Ideally, interactome networks must be expanded to cover not just a reference sequence for each gene, but all proteoforms of all genes (Smith *et al.*, 2013). With continuous development of new technologies and increased throughput this goal may soon be tackled. Incorporating quantitative, spatial, and temporal properties of interactions into networks is crucial toward generating dynamic interaction networks (Ideker and Krogan, 2012; Ge *et al.*, 2003). The ultimate aim is to obtain or infer dynamic interactome maps across different cellular conditions enabling pursuit of a 1000 interactomes project in analogy to the 1000 genomes project (1000 Genomes Project Consortium, 2010).

A more complete picture of the interactome of a cell requires elements from all of the types of protein-mediated interactions described here. There is an urgent need to expand current mapping efforts for understudied types of interactomes to match the pioneering work done for PPI, PDI, and PSMI interaction maps. Combining molecular interaction data of different types into a unified network model will enable the study of information flow from outside the cell, across the membrane, through the cytoplasm and into the nucleus to alter gene expression, altered expression that then remodels the interaction network and shifts the cell from one cellular state to another. Such integrated models promise to better represent the physiological states of a cell.

Metabolomics in Cell Biology

Introduction

The dogma that the genome has global and overall control over the processes occurring within living systems especially when they are adapting to new environments has become the preeminent tenant within biology. This is at best an oversimplification of the situation as there are multiple control systems operating with both feed-back and feed-forward inhibition or stimulation operating as controls over the system as a whole. Undoubtedly the genome as the repository of the blueprints of the cellular machinery and Jacob and Monod stated “The synthesis of enzymes in bacteria follows a double genetic control.” (Jacob and Monod, 1961), arguably leading to the belief that all the cellular processes are solely under the control of the genome, as shown in Figure 1(a), where in reality there are multiple complex feed-back and feed-forward controls between and within the groups (Fell, 1992; Kitano, 2002), a simplified view being shown in Figure 1(b).

It is errors and lack of precision within the system that allow for adaption, if an organism is living in a stable environment then it makes evolutionary sense to develop. It may seem to be simply a philosophical debate, but systems biology has set out to explain how these organisms adapt to environmental changes and what the controls over this adaption are.

The small molecule complement of an organism is called the metabolome (Oliver *et al.*, 1998) and hence the measurement of the metabolome is called metabolomics. To carry out a metabolomics study can be both complicated and expensive. In the early days of metabolomics it was thought that by running a set of samples an answer about the biological significance would appear (Plumb *et al.*, 2002). Nowadays it is understood that a rigorous and disciplined approach needs to

be adopted. The steps involved in conducting a successful metabolomics study are highlighted in Figure 2 and will be discussed in detail later.

As can be seen there are a large number of factors that need to be considered when embarking on a metabolomics study, but the first and probably most important question that needs to be asked is ‘Is it necessary/appropriate to conduct a metabolomics study in this case?’ To answer this question it is important firstly to clearly define the terminology.

Metabolomics – is a set of none targeted and unbiased analysis which attempts to analyze the whole metabolome.

Metabolite profiling (or targeted metabolomics) – is a targeted analytical approach which attempts to quantify a specific set of metabolites.

Metabolomics versus Metabolite Profiling

Scientifically and simply for the ease of communication it is important to differentiate between metabolomics and metabolite profiling (Villas-Boas *et al.*, 2005a). With metabolite profiling the experimental design and set-up is simpler to both understand and perform, this approach can be viewed as an applied application of normal quantitative analytical chemistry. More than 100 metabolites can be quantified simultaneously in *Escherichia coli* (Bennett *et al.*, 2009), by the use of stable isotopes this can (and should) be used to improve both the accuracy and precision of the measurements (Lei *et al.*, 2011) and help to remove systematic errors. This data can be used to create genome scale metabolic models (Oberhardt *et al.*, 2009) and these can be extremely useful when evaluating a dataset. If we consider a hypothetical biochemical pathway composed of six metabolites A to F (Figure 3), it would appear by measuring the level of A–F we could understand the

Figure 1 Interactions between control levels in living organisms.

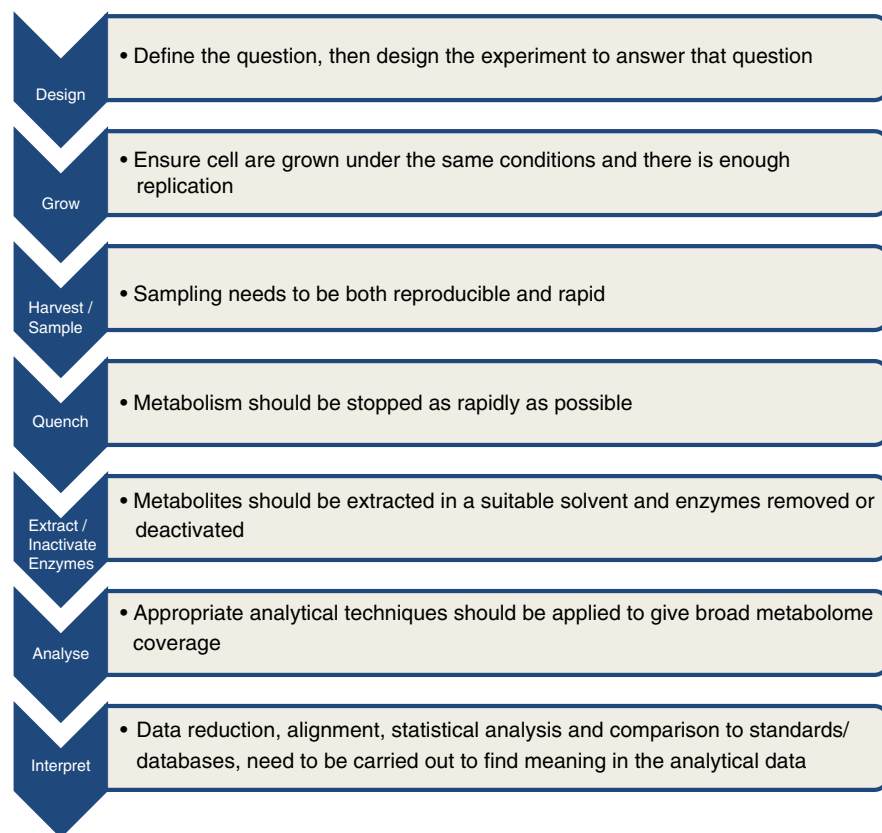

Figure 2 Seven stages that need to be considered when conducting a Metabolomics study.

Figure 3 Hypothetical 6 set biosynthetic pathway.

pathway and this is true when the pathway is functioning normally (**Figure 3-I**) but if the pathway is blocked by a nonfunctional enzyme between C and D several possible things may occur. In the case shown in 3-II where the pathway is simply blocked, metabolite profiling would be sufficient to observe an increase in the levels of A–C and a decrease in the levels of D–F. However, if a bypass shunt is established through metabolites G and H which we do not measure as is the case in 3-III and 3-IV, we would observe metabolite levels that are harder to explain.

In the case of 3-III we would observe a sudden decrease in the levels of D and E and 3-IV the pathway may well appear to be functioning normally. The use of metabolomics however would reveal the operation of the unexpected shunt.

Metabolomics does have several disadvantages when compared to metabolic profiling. These included the fact that metabolite levels are generally reported at relative levels rather than absolute, many of the possible metabolites identities are unknown or at least not confirmed. Probably the thing that puts people off carrying out metabolomics experiments is that they can be difficult to conduct as well as interpret ([Camacho et al., 2005](#)) and determine the biological significance.

Conducting a Successful Metabolomics Study

With the challenges previously outlined in mind for the rest of this article we will try to highlight the factors which need to be

considered and what is the current state of the art. The workflow that will be used is that shown in Figure 2.

Design

The first and arguably the most important part of a metabolomics study is the planning. Experimental design like in all science is the place where expensive mistakes can be avoided. Initially the question should be asked 'is metabolomics the correct approach to generate the data to test the hypothesis under trial in the experiment.' In the early years of metabolomics it was considered sufficient to collect a set of samples and analyze them to see what fell out, this hypothesis free approach was quickly found to be a very risky strategy. It is now commonly accepted that like in all sciences a well-designed and thought out experimental plan which learns from previous studies (Broadhurst and Kell, 2006) is the best approach and can prevent expensive mistakes. It is important to consider the analytical variables to yield high-quality data (Patti *et al.*, 2012) but it is equally important to consider the biological variables.

If the experiment is not designed to answer a specific question then it is highly probable that the answer that is received will be to a question that has not been asked. To illustrate this let's consider we want to use metabolomics to find the effect of introducing a gene into yeast. Of course we would not grow two different strains as the likely outcome of that analysis would be the metabolic differences between the strains. So a more sensible approach would be to grow the wild-type strain and compare this to the engineered strain; however, it is well known that the process of engineering a strain is stressful to an organism and this stress itself can have a major influence on the metabolism. There it is likely that this analysis would yield markers for the stress caused by engineering cells (Eiteman and Altman, 2006) rather than the desired outcome which is to assess the effect of the new genes on the metabolism. Logically, the ideal experimental design to answer the question 'what is the effect of introducing a gene to a strain of yeast?' would be to compare the engineered strain to one that has been through the process of engineering but with an empty vector.

In the above example it was decided that the optimal experimental design to answer the question 'what is the effect of introducing a new gene to an organism?' is to compare it to an empty vector control. However, this would make it appear that it is possible to achieve the answer by the analysis of two (possibly three, if a blank is included) samples.

Although this would be theoretically possible, it is highly unlikely that such an answer could be considered reliable and the major cause of the lack of confidence in such an answer is variability within the system. In such complex systems there are numerous sources of variability. These sources of variability can be divided into two broad classes, biological variability, and analytical variability. The biological variability is usually significantly greater than the Analytical variability. To overcome these sources of variability replication is used (Dunn *et al.*, 2005), so the next obvious question is 'how many replicates should be used?' This of course is simpler to ask than it is to answer. The level of required replication is correlated to the degree of the change that is to be assessed but generally the

more replication the better. Although currently there seems to be no reported method to evaluate the appropriate level, in our labs we always try to carry out experiments where $n > 7$.

This being said the question that comes to mind is 'what a biological replicate is?' As per normal, the answer is not absolutely obvious at first sight. A sub aliquot of an initial sample, a second sample from the same reactor, a sample of a clone grown in a different reactor under the same conditions or a different strain with the same modification grown in a different reactor under the same conditions. Although commonly used, the first two are not really good biological replicates (Fernie *et al.*, 2011), it is arguable as to which of the last two is the best biological replicate and the answer would depend on the question that is being asked. If we are asking 'what is the effect of genetic modification within a given clone' then the best biological replicate would be a sample of a clone grown in a different reactor under the same conditions. However, if we are trying to judge the effect of introducing a specific gene then a different strain with the same modification grown in a different reactor under the same conditions would be the preferred biological replicate. Once again we come back to the concept that we must ask the correct question to design the experiment.

So far we have only considered the simple case of a pair-wise comparison at a single time point, but the same considerations are valid when comparing multiple strains (this can be viewed as doing multiple pair-wise comparisons) or when looking at temporal variation.

It is important to consider what types of samples will be required to be taken during the course of the experiment; microorganisms interact with their environment by both importing into the cell and exporting from its chemicals. This means that it is possible to consider the internal metabolism of the cells known as the endo-metabolome or fingerprint and/or external metabolism of the cells known as the exo-metabolome or footprint (Tian *et al.*, 2009; Figure 4).

Growth

The use of standard and controlled conditions is of critical importance (Werf *et al.*, 2007) to the success a metabolomics study has at answering the question that was initially asked. In bioreactors factors such as temperature, pH, media, O₂, and CO₂ are readily controlled (Mashego *et al.*, 2007) but in shake

Figure 4 Representation of the endo and exo metabolome.

flasks and well plates these factors are more difficult to control. To improve mixing in well plate, the addition of a glass bead has been reported to improve mixing and hence gas transfer (Ewald *et al.*, 2009). However, for such an important area that is known to have significant effects on the response of cultured cells there is surprising little literature reporting the studies of basic factors. Factors such as edge effects due to changes in the microenvironment either in plates or within incubators are common knowledge and taken account of in well-designed experiments but little primary source materials can be found that relates to metabolomics analysis.

Harvesting/Sampling

The most important factor that affects what is the best sampling protocol to use is whether fingerprint or footprint analysis is to be carried out (see below for definitions).

Footprint analysis: This is arguably the easier of the two analyses, as only the levels metabolites in the media are measured; the sample prep for this can be as simple as centrifuging an aliquot of the media prior to analysis (Pope *et al.*, 2007) or sterile filtering (Dorries and Lalk, 2013). Generally, it is assumed that the media can be expected to be in a steady state condition during the time scale of the sampling and therefore the exact sampling protocol is less important than the fact that it is carried out accurately and reproducibly for the samples in the batch.

There are two commonly applied techniques to measuring the fingerprint metabolome of microorganisms and the two approaches differ as to whether or not the cells are separated from the media for the fingerprint analysis to be carried out.

The two techniques are:

1. Differential analysis

In differential analysis two aliquots of the media are taken, the cells are removed from one, either by filtration or centrifugation. The two extracts are then analyzed and the differences in the metabolites and their levels allow the determination of the fingerprint metabolome (Taymaz-Nikerel *et al.*, 2009).

2. Isolated cell analysis

In isolated cell analysis, the cells are removed from the media by filtration or centrifugation and then they are lysed to extract the metabolites prior to analysis, this of course seems to be the simplest approach to take, however it has been noticed that cells can undergo significant metabolic changes during the process of isolation from the media, due to entering a state of starvation. To prevent this, generally cells are quenched through fast changes in either temperature or pH, during sampling process to stop all metabolic activity (Villas-Boas *et al.*, 2005b) (this will be discussed further below).

Whichever type of analysis is going to be carried out, it is clear that the time required to take the sample may significantly affect the results. The most important thing, however, is to ensure that all the samples within a set are treated identically, to ensure random errors are minimized. As to which technique is most appropriate for a given organism, as per usual in the field of metabolomics there are many approaches that can/should be tried to find the one that is most appropriate,

such as fast sampling (van Gulik, 2010), forced air *in situ* sampling (McCloskey *et al.*, 2014a), fast filtration (McCloskey *et al.*, 2014b). It is generally accepted that if the intracellular metabolome is to be measured then a rapid sampling technique/device (such as the one in Figure 5) should be used.

Quenching

Once the sample has been taken from the fermentation vessel if intracellular metabolites, which are turned over rapidly, are being measured, it is important to stop the metabolic processes as quickly and completely as possible. This process is known as quenching and can be done by rapidly increasing temperature, rapidly decreasing temperature or significantly changing the pH. As to which technique is most appropriate for a given organism there are many approaches that can/should be tried to find the one that is most appropriate (Table 1).

Extract/Inactivate Enzymes

If quenching has been carried out using one of the 'cold' methods, when the sample warms up the enzymes that are present are likely to have significant activity and change the levels of the metabolites in the sample. In the extraction process, the aim is to extract all the metabolites that are present whilst leaving behind proteins, enzymes, and contaminants. This unfortunately is not possible, and any extraction solvent that is used will discriminate between various classes of metabolite, again the key is to treat all the samples in the same way. There are numerous extraction solvents/technique reported in the literature, the most common are acidic acetonitrile/water, boiling water, boiling ethanol, or methanol. Once again it is advised several techniques are tried prior running a large experiment. It is important to keep in mind that the more complex the technique used the more prone it is to errors and hence variability. As there is no 'one size fits all' extraction protocol, it is advisable to match the extraction method with the analytical method, for example, if looking for lipids and aqueous extraction is probably not advisable whereas chloroform/methanol may be very suitable but you would not expect to see nucleotides in that extract.

As metabolomics ultimately relies on statistical analysis of the data to elucidate any differences between the treatment groups, it is extremely important that the potential sources of error are understood and that the analytical data collected is as reliable as possible. There are several types of samples that can and should be run as part of a batch (Table 2).

To improve the reliability and reproducibility of the acquired data the normal analytical chemistry approach would be to use isotopically labeled internal standards, however this is impractical in the case of metabolomics as it would be cost prohibitive. However it is possible to use cell extracts from cell uniformly ¹³C-labeled sole carbon source as internal standards (Wu *et al.*, 2005). This approach allows correction for changes in instruments sensitivity during the analysis of a batch of samples. If this approach is to be used as mentioned previously the appropriate extraction system should be chosen for the analysis, using the isotopically labeled extract as the extraction solvent can be helpful in reducing the effects of losses during extraction.

Figure 5 Low dead volume sampling device (design provided by Prof. Walter M. van Gulik, Delft University).

Table 1 Some common quenching techniques

Heat	Boiling 75% ethanol with 70 mM-Hepes	Gonzalez et al. (1997)
	Boiling water	Wittmann et al. (2004)
Cold	Cold glycerol-saline	Villas-Boas and Bruheim (2007)
	Cold phosphate-buffered saline	Teng et al. (2009)
	Cold 60% methanol solution	Winder et al. (2008)
	Cold 60% methanol with 0.85% ammonium bicarbonate	Sellick et al. (2008)
pH	Perchloric acid	Theobald et al. (1993)
	2 M KOH solution	Theobald et al. (1997)

Analyze

Similar to the fact that there is no one extraction solvent that is suitable for the extraction of the entire metabolome, there is no single analytical technique that enables the analysis of the

complete metabolome. The type of molecule each technique is applicable to is shown in [Figure 6](#). To increase the coverage of the molecules analyzed it is not uncommon to run multiple analytical techniques ([Meyer et al., 2010](#)).

It is widely accepted that mass spectrometry is the technique of choice for metabolomics experiments, with the one exception of direct infusion mass spec, all single stage mass spectrometer can be thought of as consisting of three functional units ([Figure 7](#)).

There are two separation techniques that are commonly used for metabolomics analysis, gas chromatography (GC) and ((ultra) high performance) liquid chromatography (((U) HP)LC).

GC is generally used for the analysis of volatile compounds (i.e., relatively small and nonpolar) or compounds that can be made volatile by chemical modification (derivatisation). There are many possible derivatisation reagents available each of which varies in their reactivity and the classes of compounds they are useful for. Probably the most generic derivatisation reagents are the trimethylsilyl group (TMS) such as *N,O*-Bis(trimethylsilyl)trifluoroacetamide (BSTFA) or *N*-Methyl-*N*-trimethylsilylfluoroacetamide (MSTFA) ([Kanani et al., 2008](#)). The second group of commonly used derivatising reagents are the alkylating reagents such methylchloroformate (MCF)

Table 2 Type of samples to be run during a Metabolomics study

Sample	Subclass	How it is made	Purpose
Blanks	Solvent Blank	Extraction solvent in clean vial	To check for carry-over especially after high level standards
	System Blank	Extraction solvent put through the extraction process just with no sample	To allow the identification of contaminants that are introduced during the sample processing
Replicates	Technical	A second extract of a sample that has been split (from same flask at same time)	To show that the extraction and analysis are reproducible
	Analytical	A second injection of a sample that has been injected	To show that the analysis is reproducible
	Biological	A second extract of a sample that has been grow under the same conditions (from different flask at same time)	To show the level of biological reproducibility
QC/Controls	Pooled	An equal volume of the extract from all the samples in a batch	To show the level of temporal drift in the analysis
	Xenobiologic	Extract of a non-related organism that has a different metabolome	To show the whole system can differentiate reliably between different metabolomes
Standards	RT standards	Set of known compound at different retention times (rt)	To allow for rt to be adjusted over time during the course of a large study and allow comparisons between studies run at different times
	ID standards	Known compound in solution of suitable solvent at known concentrations	To allow the identification and/or quantification of unknown compounds

**Figure 6** Graphical representation of the analytical technique applicability.**Figure 7** Function representation of a mass spectrometer.

(Villas-Bôas *et al.*, 2003). When a GC is coupled to a mass spectrometer the most common method of ionizing the analytes is by bombarding them with electrons at a known energy (electron ionization (EI)). The energy imparted by the electrons cause the ejection of an electron from the analyte and hence it becomes an ion, the excess energy causes the ions to fragment in reproducible and predictable ways. The fragmentation patterns observed in EI–GC–MS analysis can be

compared to commercially available libraries to aid identification of unknown analytes, but care should be taken. These library identifications should be treated as indicative and not as definitive. To truly confirm the identification of an analyte an authentic standard should be run along with a coinjection with the sample. GC–MS (Figure 8(a)) provides the primary analysis technique for the analysis of volatile and semi-volatile analytes.

For the separation of larger and more polar analyte, LC is generally preferred over GC. By far the most commonly used separation carried out on LC systems a reverse phase method, based on the C18 column, these columns however do not retain very polar analytes, although with the advent of aqueous C18 columns this has improved. To analyze very polar analytes it is common to use an orthogonal separation approach known as hydrophilic interaction chromatography (HILIC). Both of these separation techniques are generally coupled to a mass spectrometer by an electrospray ion source (ESI) to form an LC–MS system (Figure 8(b)), the LC eluent passes through a needle that is held at an electrical potential relative to mass spectrometer and as the sprayed droplets evaporate they become ionized. ESI is known as a soft ionization technique as it has a tendency to form molecular ions/adducts with little fragmentation. However, if the separation is incomplete then the co-eluting analyte compete for the charge which can cause the measured level of one of the compounds to be lower than it actually is. Electrospray can be run in either positive or negative ion mode and it is advisable to run the batch of sample in both modes. In many cases it is possible to switch alternatively between the ionization modes but this effectively halves the data acquisition rate so in many labs running a sample in positive mode and then rerunning it in negative mode is preferred. Electrospray ionization is not very suitable for

Figure 8 Schematic of (a) GC-MS and (b) LC-MS system; I: Separation method, II: Ion source, III: Mass analyzer, IV: Detector, and V: Turbopumps.

the analysis of analytes of low polarity such as lipids, for these types of molecules another type of ionization is used this is known as atmospheric pressure chemical ionization (APCI).

There are still issues with the separation and analysis of extremely polar and extremely nonpolar metabolites. To analyze polar analytes there are two commonly used approaches ion-pairing (Lu *et al.*, 2010) or capillary electrophoresis (Soga *et al.*, 2003). For the analysis of nonpolar analytes supercritical fluid chromatography (SFC) has started to remerge as a technique of interest (Bamba *et al.*, 2008).

From the previous discussion it can easily be seen that multiple technique need to be use to attempt to achieve a study that yields the broadest range of metabolites as possible, even though it will not be truly complete.

Data Interpretation

Once the data from a well-designed and well-executed non-targeted metabolomics experiment have been collected, it needs to be analyzed to give meaning and biological relevance to the data. These stages are still very active areas of research and can be divided into two primary areas, data reduction and data analysis.

GC-MS data

The electron impact or electron ionization (EI) as it is also known is the most common method of ionization used in GC-MS analysis and as stated previously as well as ionizing

the molecule in the majority of cases it causes the ion to fragment. As long as the energy of the electrons are at the standard accelerating voltage of 70 eV the resultant spectra should be reproducible and therefore can be searched against the reference databases or can be worked out from the structure (Figure 9(e)). An examination of the EI spectra (Figure 9(b) and 3(d)) it is apparent that no ion that corresponds to the ion from the intact molecule can be seen, this is not uncommon in GC-MS, however, this can hinder the identification of unknowns. It cannot be stressed enough that the identification of a compound by a database search

should only be counted as indicative and little confidence should be placed on such identifications. Where ever possible confirmation of such identification should be made by the injection of an authentic standard under the same condition or even better is to also run the authentic standard mixed with the sample. In complex samples such as cell extracts or media it can be difficult to get a spectrum that is from only one compound, in this case mathematical algorithms can be used to tease apart the spectra and assign each ion to the correct spectrum, this is known as deconvolution.

Figure 9 An example of GC-MS data; (a) (Top) The total ion chromatogram (TIC), (Bottom) Extracted ion chromatogram (XIC) of the 302 ion for a TBDMS-derivatised acid hydrolysate from yeast; (b) Spectrum from the peak at a retention time of 13.06 mins which has a suggested identification of TBDMS-Tyrosine when search against NIST DB; (c) (Top) The total ion chromatogram (TIC), (Bottom) Extracted ion chromatogram (XIC) of the 302 ion for a TBDMS-derivatised Tyrosine standard; (d) Spectrum from the peak at a retention time of 13.06 mins for TBDMS-derivatised Tyrosine standard; (e) Possible fragments for TBDMS-derivatised Tyrosine.

LC-MS data

In LC-MS the most common ionization technique that is used is electrospray (ESI), in which the solvent which has been used to elute the column is passed through a needle which is held at an electrical potential relative to the orifice on the mass spectrometer. As the droplets travel through the air in the source they evaporate and the charge on them increases up to the point where it overcomes the surface tension. At this point the droplet breaks apart and the ion is formed, if there is more than one compound within the droplet then the compound can compete for the available charge and the ionization of one of the compounds may be suppressed (this is known as ion suppression), this is why good chromatographic separation is extremely important in metabolomics experiments and why I am not a supporter of direct infusion mass spectrometry for metabolomics. ESI is a soft ionization technique which means that the ions that are formed tend to contain the intact molecules and little or no fragmentation occurs. However there can be a tendency to form adducts with components within the solvent or at high concentration form multimers where an ionized molecule shares its charge with one or more unionised molecules (**Figure 10(b)**). Dependent on the capabilities of the instrumentation used to collect the data the number of possible identifications can be vast if only MS^1 is used. The number of possible identities can be reduced by the use of higher order MS analysis which cause the ions to fragment by colliding them with gas molecules, leading to fragments that at first sight resemble those seen in GC-MS but as there is no standard for these types of collision-induced dissociation in LC-MS there is no database available for the reliable identification of unknown molecules especially when comparing data acquired on instruments from two different vendors. If an instrument is capable of acquiring accurate mass data it is possible to drastically reduce the number of possible elemental formulas for an unknown compound (**Kind and Fiehn, 2006**), however this is far from being an identification. Best practice would have both higher MS analysis and accurate mass to aid in identification of unknowns, this remains as one of the major challenges in metabolomic analysis.

The data reduction stage can be further divided into deconvolution, alignment, and normalization (**Katajamaa and Oresic, 2007**). The output from this stage should be a table of the response for each peak/feature for every file. There are many both commercial and freeware products available that will enable some or all of the data reduction to be automated, however, the controls, qc samples, and replicates should be used to validate the results that are obtained.

Data analysis of the tabular data is usually conducted using a type of discriminate analysis; by far the most used (and probably abused) is principle component analysis (PCA). PCA is generally a good starting point to quickly visualize and data quality check. There are easy to use data analysis tools that are available online (**Xia et al., 2012**).

As stated previously to place statistically significant peaks in biological context they must be identified, so they can be mapped onto the metabolic networks. This step can be both extremely difficult and time consuming. With GC-MS analysis yielding the peaks of interest, a good starting point in the process of identification is searching against commercially

available libraries and then any putative identification can be confirmed by use of authentic standards. Chemical ionization (CI) can be used to try to find the molecular weight which can help narrow the search space. CI is a softer ionization technique than EI however, it still somewhat of a 'black art' being more complex to set up than EI. Another recent development in the GC-MS is the advent of 'affordable' accurate mass instruments which have a great deal of potential to improve the reliability and ease of identification of unknown peaks.

For LC-MS, these commercial libraries are not widely available so other approaches are needed, such as MS^n and/or accurate mass analysis. MS^n can give fragmentation patterns (like GC-MS) that give structural information but due to the lack of standardization between vendors these tend vary between instrument types. Accurate mass analysis (if carried out at a sufficient accuracy) can yield a short list of possible elemental formula, but even if one elemental formula is found it is highly likely that there will be significant number possible chemicals of that formula. A combination of both MS^n and accurate mass analysis coupled with biological context is the best way to approach the identification of unknown peaks. Similarly to GC-MS, when a putative identification has been made, at the very least an authentic standard should be run but better than that is co-injecting the authentic standard with a sample containing the peak of interest.

If UL-isotopically labeled cell extracts are used as internal standards in both GC-MS and LC-MS, this can be a significant help in compound identification, as the mass difference between the unlabeled ion and the labeled one can be used to calculate the number of carbon atoms in a molecule for both fragments and molecular ions. This technique can be extremely powerful so long as all the carbon sources are fully labeled, i.e., no carbon is being fixed from CO_2 . Once a significant compound has been identified, it is good to show a biological effect of the compound although this is not always possible.

Using Metabolomics Data (What Good Is It?)

The aim of any metabolomics experiment is to draw conclusion from the data that leads to gaining an increased understanding of the biological system. The use for metabolomics data depends very much on whether or not statistically significant components can be identified. In the case where they have not/cannot be identified, it is possible to use these components as potential biomarkers for the particularly different conditions tested in the original experiment. However such biomarkers should be validated for the predictive power for the conditions they will be used to differentiate between especially when it come to the use to aid in medical diagnosis (**Koulman et al., 2009**). The inability to identify unknown peak/components has undoubtedly lead to the popularity of metabolite profiling where the data is significantly easier to interpret although runs the risk of experiments being designed that can significantly over estimate a metabolites importance within a biological process. However if significant peaks in an untargeted metabolomic experiment can be identified then the levels can be used to help create metabolic models (**Kell, 2004**), which can in turn be used to predict an organisms response to a particular challenge. It is likely that only the

Figure 10 An example of LC-MS data; (a) The total ion chromatogram (TIC) of a sample; (b) Spectrum from the peak at a retention time of 3.11 mins marked with the *. In the insert ion I at m/z 503 corresponds to the molecular ion, II at m/z 549 corresponds to the formate adduct, III at m/z 539 corresponds to the major chloride adduct, the ion in the made spectrum at m/z 1007 corresponds to the dimer; (c) the MS2 spectrum of the molecular ion (m/z 503), (d) possible fragmentation route for the molecule.

metabolomics experimental approach will enable us to fully understand the metabolic processes and capacity of cells, as it has the potential to allow the discovery of unknown/unlikely metabolic pathway cell can adopt when under stress.

The Future and Notes of Caution

Metabolomic is still in its infancy as an approach to deciphering complexity in biological systems but does show great promise (Harrison and Herrgard, 2013). Initially metabolomics was viewed as being able to answer question which you did not even know to ask. Over the past decade or so it has become more apparent that metabolomics is better suited as a discovery technique which enables a better question to be formulated for more targeted experiments. As instruments improve the volumes of data that can be acquired increases vastly but simply collecting data has not been shown to be a useful use of time and resources. To be successful metabolomics requires good communication between a multidisciplinary team, who formulate a robust, rigorous and appropriate experiment, which then is executed in a scientific and disciplined manner.

Introduction

The cell is a highly complex system of molecules that carry out an astonishing number of functions. Individual molecules, including genes, RNAs, proteins, and metabolites are the building blocks of the cell, but most cellular activities only arise from interactions among these elements. Over the last 50 years, molecular biology has introduced many useful ways of describing combinations of proteins that function together. These descriptions include signaling and metabolic pathways, gene regulatory modules, etc. Pathways have been summarized in various publicly available resources, such as Gene Ontology (GO) ([The Gene Ontology Consortium, 2000](#)), KEGG ([Kanehisa and Goto, 2000](#)), Biocarta ([Nishimura, 2001](#)), Reactome ([Vastrik et al., 2007](#)), etc. Although current knowledge of pathways, especially in the context of human biology, remains incomplete, it serves as a useful starting point for many analyses.

Nevertheless, the functional interactions of genes and proteins can be highly dynamic, depending on context and condition. Technological innovations for high-throughput measurements have helped to fill in many missing components of pathways and to reveal the extent of these dynamic links. These methods include RNA sequencing (RNA-Seq), chromatin immunoprecipitation followed by sequencing (ChIP-Seq), mass spectrometry, and RNA interference screening. Each technology type provides a different snapshot of the state of a cell. RNA-Seq experiments capture transcriptional changes, ChIP-Seq data capture changes in transcription factor binding, RNAi screens assess the role of individual genetic perturbations, and drug compound screens measure the effects of individual chemical perturbagens on cellular state.

These technological advancements have created a need to move from analysis of individual pathways to global

interaction networks, a concept that emerged with the completion of the first genome projects in the 1990s. Mathematically, a network can be described as a graph, which consists of nodes (in this case molecules) and edges (interactions). There is a rich literature on algorithms for analyzing such graphs. In this article, we will examine some of the computational methods that have been developed to analyze biological networks ([Table 1](#)). We will emphasize those approaches that integrate multiple, disparate data types to provide testable hypotheses.

Overview

We have structured this article according to the complexity and diversity of the types of data integrated by each method. We have sampled from a range of methods with very different approaches to similar problems. We begin with algorithms that analyze a 'single data source' such as mRNA expression or metabolomic data in the context of a known protein–protein or protein–DNA interaction network. Next, we examine methods that analyze networks together with 'more complex data types,' such as somatic mutation and copy number variation data. Finally, we examine methods that 'integrate data types that capture a hierarchical flow of biological information.' For example, a chemical trigger, such as a DNA damage agent, may generate a transcriptional cellular response. Methods in this category reveal the signaling and regulatory sequence of steps that lead from the chemical perturbation to the activation or inhibition of the relevant transcription factors, which subsequently cause activation or repression of the expression of relevant target genes. Most of the methods in this group bridge genetic, chemical, or phosphoproteomic perturbations and their downstream gene

Table 1 Overview of network methods

<i>Method</i>	<i>Type</i>	<i>Separate genes/proteins</i>	<i>Data source</i>
jActiveModules	Simulated annealing	No	Gene expression
GXNA	Greedy algorithm	No	Gene expression
ClustEx	Clustering	No	Gene expression (time course)
SAMBA	Biclustering	No	Gene expression
cMonkey	Biclustering	No	Multiple data sources
NetWalk	Random walk	No	Gene expression
RegMod	Regression	No	Gene expression
Dendrix	Greedy approach; Markov chain Monte Carlo	No	Somatic mutation data
MeMo	Correlation analysis and statistical tests	No	Somatic mutation, copy number variation data, and gene expression
HotNet	Diffusion-based algorithm	No	Somatic mutation
TieDie	Diffusion-based algorithm	No	Somatic mutation and gene expression
ResponseNet	Network flow; linear programming	Yes	Multiple sources: gene expression, phosphroteomic, and genetic data
Prize-collecting Steiner Tree	Message-passing; linear programming	Yes	Multiple sources: gene expression, phosphroteomic, and genetic data
Prize-collecting Steiner Forest	Message-passing approach	Yes	Multiple sources: gene expression, phosphroteomic, and genetic data
CircadiOmics	N/A	Yes	Multiple sources: gene expression and metabolomics data
rFBA	Flux-balance	N/A	Metabolomics data
idFBA	Flux-balance	N/A	Metabolomics data
iFBA	Flux-balance	N/A	Metabolomics data
IOMA	Quadratic programming	N/A	Multiple sources: metabolomics and proteomic data
PARADIGM	Message-passing approach	Yes	Multiple sources

expression responses using protein–protein, protein–DNA, and other types, such as kinase–substrate interactions.

We close by examining a critical issue that has been largely ignored in most network approaches: To what extent can gene expression data be used as a proxy for protein levels? While most studies conflate these two, it is now abundantly clear from high-throughput analyses that the correlation between these data is very poor. We close by speculating on where a more realistic modeling of different types of data will lead the field.

Network Algorithms

Integrating a Single Data Source with an Existing Interaction Network

In this section, we describe several different approaches to the identification of functionally active groups of genes based on a single data source and a known interaction network. The tools we characterize in this category use a variety of methods, including simulated annealing, clustering and biclustering, as well as greedy, regression, and random walk-based approaches.

One of the first solutions to this problem was a ‘simulated annealing-based approach’ to finding ‘active’ subnetworks (Ideker *et al.*, 2002). The algorithm, called jActiveModules, uses gene expression data, protein–protein, and protein–DNA interaction data to identify connected groups of genes,

represented as nodes that exhibit significant differential expression under one or more conditions.

Briefly, the method can be summarized as follows: the algorithm starts with edges defined by known protein–protein and protein–DNA interactions and assigns an estimate of significance to each gene based on the change in its expression level, expressed as a *z*-score (Ideker *et al.*, 2002). The *z*-scores are used to search for high-scoring subnetworks using simulated annealing, where a subnetwork is assigned a combined *z*-score calculated from all the included genes. In the annealing step, a node is included and assigned an active/inactive state, which is initially toggled randomly. With each annealing iteration, the aggregate *z*-score of the subnetwork is evaluated and compared to the score from the previous iteration. If the aggregate score has improved, the node retains its toggled state; otherwise, it is kept toggled at a decreasing probability with each iteration (Ideker *et al.*, 2002). An advantage of this method is that various modifications can be applied to the annealing process, for example, multiple subnetworks can be evaluated simultaneously. However, a potential pitfall of this approach is the large size of the identified subnetworks. One alleviating solution to this problem may be to apply the process in a recursive manner to subdivide large subnetworks into more specific smaller subgraphs.

One alternative to simulated annealing methods is the ‘greedy’ class of algorithms. GXNA (Gene Expression Network Analysis) (Nacu *et al.*, 2007) is an example of such a greedy-based approach. GXNA uses mRNA expression and protein–protein interactions to identify functionally active gene subnetworks. Nodes are defined as genes, while edges

correspond to protein–protein interactions. The method first assesses the significance of differential gene expression for every node. Then, it selects a seed vertex and expands the subnetwork from the seed vertex by adding nodes connected to the vertices already in the subnetwork with the goal of maximizing the overall subnetwork score (Nacu *et al.*, 2007). The overall score is defined in one of two ways: as an average of individual gene test statistic scores or as a test statistic based on the average of individual gene expression values. The algorithm stops when the subgraph reaches a certain prespecified size. This approach resolves the issue of subnetwork size, but it suffers from another potential problem, more characteristic of greedy approaches, i.e., the possibility of getting stuck in local maxima.

‘Random walk-based methods,’ such as NetWalk and FunWalk, present another approach. NetWalk (Komurov *et al.*, 2010) is an example of a random walk-based algorithm, which uses the whole distribution of mRNA expression in an experiment in the context of network connectivity to identify functionally active groups of genes. Nodes represent individual genes, while edges correspond to protein–protein interactions. The algorithm assesses the centrality of genes in the network, but instead of using only a small set of differentially expressed (DE) genes revealed by the gene expression data, it uses the entire data distribution. Notably, the transition probabilities between nodes are biased according to the data values associated with individual genes, i.e., higher data value genes receive higher visitation probabilities, while lower data value nodes are assigned low visitation probability. The algorithm generates individual edge flux (EF) values, where an EF edge score represents how important the interaction is as measured by the data (Komurov *et al.*, 2010).

A completely different approach to the identification of disease-associated groups of genes, based on the integration of protein–protein interaction data and gene expression data is the formulation of the method RegMod (Qiu *et al.*, 2010). RegMod uses a ‘regression’ model with a diffusion kernel to efficiently identify significantly dysregulated modules of genes. In the context of this method, nodes represent genes, while edges represent protein–protein and protein–DNA interactions between pairs of genes (Qiu *et al.*, 2010). The weight of an edge between two genes is given by the Pearson correlation coefficient of the similarity between the expression profiles of those genes. Each node has a weight associated with the activity of its corresponding gene. However, while a node’s weight is usually the differential expression change of a gene between a pair of conditions, in this context, the weight of a given node is a function of the weights of its neighboring genes.

The final group of methods in this category is ‘clustering and biclustering’ algorithms. ClustEx (Gu *et al.*, 2010) is a two-step hierarchical clustering method that incorporates mRNA expression, especially time-course mRNA expression, and protein–protein interaction data. The goal of the method is to identify tight functional clusters of DE and potentially directly interacting genes. Nodes are defined as genes, while edges between nodes are defined as direct protein–protein interactions. The distance between directly interacting genes is inversely correlated with their level of co-expression, as measured by the mRNA expression data, while the distance between any pair of genes is the shortest path between them as identified using Dijkstra’s algorithm. All shortest paths are calculated in the first step of the algorithm,

and hierarchical clustering with average linkage analysis is used to identify clusters of DE genes. In the second step, the method incorporates other (intermediate) genes, not found in the clustering step, into the gene modules. These intermediate genes could be either DE genes, genes on the *k*-shortest paths between DE genes, or first neighbors of either of those types. Finally, the algorithm determines the statistical significance of the modules by edge scrambling, i.e., random rewiring of the edges in the network to different node pairs.

While normal clustering generally compares conditions by evaluating similarity of expression across all genes in a sample, biclustering, by contrast, compares conditions using only a subset of the genes that maximize the similarity of the conditions. As a result, biclustering can identify a subset of genes that show a similar pattern over a subset of conditions and here we focus on a couple of more recent biclustering algorithms.

SAMBA (Tanay *et al.*, 2002) is a network-based biclustering algorithm, which uses a mixture of graph-theoretic and statistical models to identify groups of genes with similar patterns of expression over a subset of samples or conditions. SAMBA defines a vertex for every gene and condition, and an edge between a pair of vertices if the pair exhibits significant changes in expression in the given condition (Tanay *et al.*, 2002). The problem is then reduced to identifying a maximum weight subgraph, or more specifically a maximum edge weight biclique, where the weights on vertex pairs in the subgraph rely on a likelihood-based score and correspond to a measure of the significance of the subgraph.

The cMonkey (Reiss *et al.*, 2006) method is an iterative biclustering algorithm, which builds on gene expression, but also incorporates additional components, such as motif co-occurrence, metabolic pathway co-occurrence, or protein network association, etc. The overall score is a mixture of the scores of individual components, where each element is weighed individually to assess its contribution to the final score. A *p*-value is measured for each scoring unit; for example, if the sequence component of the score is assigned a nonzero contribution weight, the ‘motif *p*-value’ is defined as the significance of co-occurrence of motifs within the member genes of a subcluster (Reiss *et al.*, 2006).

Once an initial seed subcluster of conditions and genes is identified, the cluster is improved by iteratively calculating the conditional probability of membership for each gene and condition and then sampling from it to add to or remove genes and conditions from the cluster. Once a cluster stabilizes, the algorithm identifies a new ‘seed’ subcluster and follows the same process.

Metabolic Networks

The methods described above largely use high-throughput protein–protein and protein–DNA data to build the underlying networks. Recently, there have also been interesting attempts to understand how changes in gene expression alter metabolic networks. Historically, metabolic networks have been analyzed by completely different methods from ‘omic’ data. The main goal in metabolic network analysis has been predicting flux through reactions using linear programming.

These methods determine the optimal flow through a network where the nodes represent metabolites and the edges represent chemical transformations. In order to determine the optimal flux through the network, one must specify an objective function. The choice of this function has been a subject of some debate (Covert and Palsson, 2002).

One example of a very context-specific algorithm is Circadiomics (Patel *et al.*, 2012), which identifies network connections between transcriptional changes and metabolomic data, specifically associated with circadian rhythm (Covert and Palsson, 2002). Methods including rFBA (flux-balance analysis) (Lee *et al.*, 2008), integrated dynamic FBA (idFBA) (Covert *et al.*, 2008), and integrated flux-balance analysis (iFBA) (Yizhak *et al.*, 2010) use enzyme expression levels to influence the flux through metabolic pathways. Integrative omics-metabolic analysis (IOMA) (Abreu *et al.*, 2009) integrates proteomic and metabolic data in a similar fashion.

Complex, Cancer-Related Genetic Networks

The identification of significantly dysregulated pathways in different cancer subpopulations has presented a tremendous therapeutic challenge, to which integration of multiple layers of information, such as copy number variation, somatic mutation information, and mRNA expression present a possible solution. The sequencing of cancer genomes raises the possibility of using somatic mutation information collected from a large number of patient samples to identify significantly dysregulated pathways and relevant somatic driver mutations in different cancer subpopulations. Several algorithms have been developed to address the challenges and we discuss some of these tools in this section. We first introduce the algorithms Dendrix (Vandin *et al.*, 2012) and MeMo (Ciriello *et al.*, 2012), and then proceed with the network propagation and diffusion-based algorithm HotNet (Vandin *et al.*, 2011) and TieDie (Paull *et al.*, 2013).

Dendrix (De Novo Driver Exclusivity) describes a pair of algorithms that searches for subsets of genes that show high mutational load, i.e., exhibit mutations across most patient samples in a dataset (high coverage), but in a mostly mutually exclusive manner (high exclusivity) (Vandin *et al.*, 2012). The logic behind these requirements is that important cancer developmental pathways will show perturbations across a large number of patients for a given cancer type. However, while mutations in a single gene may be sufficient to dysregulate the activity of the pathway, multiple mutations may be unlikely to occur in a single gene and patient. This idea is formulated as a maximum coverage exclusive submatrix problem, where the matrix represents mutation presence in a gene (column) for a patient (row), and the problem refers to identifying mutually exclusive submatrices with the largest number of nonzero rows (patients) (Vandin *et al.*, 2012). The trade-off between strict mutual exclusivity and maximized patient coverage leads to a reformulation of the question as a maximum weight submatrix problem. Dendrix uses both a greedy approach and Markov chain Monte Carlo approach to identify relevant exclusive subsets of genes with a high mutational load (Vandin *et al.*, 2012).

An alternative method, MeMo (Mutual Exclusivity Modules in Cancer) uses a graph-theoretic approach to a very similar

problem (Ciriello *et al.*, 2012). Similar to Dendrix (Vandin *et al.*, 2012), the goal of this method is to identify sets of driver genes that show significant dysregulation and mutation across most conditions (i.e., patient samples), are likely to belong to the same pathway, but show alterations in a mutually exclusive manner. The algorithm uses a four-step approach, which starts with the application of several filters to identify significantly mutated genes (using somatic mutation data), or genes that fall within genomic regions with a recurrently altered copy number (using copy number variation data), both of which have to show concordant changes in mRNA expression (using mRNA expression data). These changes are encoded in a binary event matrix and the method then identifies pairs of altered genes that are likely to belong to the same pathway, based on known pathway and interaction database information. The algorithm builds a network of all such gene pairs, extracts maximal cliques, and measures the mutual exclusivity of individual cliques.

One potential caveat of some of these methods is study bias, where well-studied genes and proteins are most likely to be incorporated into a significant subgraph primarily because of their high level of connectivity, i.e., random set of genes can easily include these well-connected hub-like proteins (Vandin *et al.*, 2011). Methods, such as the ones we describe next – HotNet (Vandin *et al.*, 2011) and TieDie (Paull *et al.*, 2013) – attempt to remedy this problem by using network diffusion, where information diffuses from network nodes in a manner similar to heat diffusion.

HotNet (Vandin *et al.*, 2011) builds on the concept of identifying subgraphs of DE genes. Its goal is to identify significantly mutated subnetworks, i.e., groups of genes mutated more than expected by chance. As in other methods, here nodes designate proteins and their corresponding genes, while edges represent protein–protein or protein–DNA interactions. The algorithm defines an influence diffusion-based measure on a pair of genes, such that a gene influences another gene if they are proximal in the graph and if there are only a small number of paths between them. The rationale behind the latter requirement relates to the desire of avoiding the identification of subnetworks of mutated genes connected primarily through uninteresting high degree (hub-like) proteins. HotNet builds its influence graph using only genes that have been assayed for mutations, but it takes into account the connectivity of all genes. It identifies subgraphs of genes mutated in a large number of samples (patients), but the number of mutations associated with each gene can be additionally used to weigh the influence score.

In all the methods described in this section, network propagation and flow-like approaches are generally used to find links among mutations that target a pathway leading to cancer. However, related approaches can also be used to search for links from mutations to their transcriptional consequences. In the next and last section of this review, we explore methods for integration of data types that capture a hierarchical flow of biological information.

Methods for Integration of Data Types that Capture a Hierarchical Flow of Biological Information

ResponseNet (Yeger-Lotem *et al.*, 2009) seeks to identify a minimum set of edges that link a set of molecular causes

(mutations, for example) and consequences (gene expression changes). This network-based optimization approach uses linear programming techniques to solve a minimum cost flow algorithm. In this network setting, vertices represent either DE genes (from transcriptional data), or significant gene or protein hits from genetic or proteomic screening efforts. Edges represent either a regulatory interaction between a transcription factor protein and a target gene, or a protein–protein interaction between two proteins. The ‘flow’ represents the set of weighted protein–protein interaction network edges selected by the algorithm that best explain the consequences with the causes. The method requires randomization to identify the most surprising nodes and interactions, given the underlying interaction network.

Many perturbations induce both a specific cellular response and a general response to stress. A multi-commodity flow implementation of ResponseNet, SAMNet (Gosline *et al.*, 2012) is designed to distinguish these two types of pathways. It uses data from multiple conditions and applies the flow algorithm with a constraint that requires that two experimental conditions must ‘share’ each edge. This forces the algorithm to identify condition-specific pathways and reduces the need for excessive randomization.

TieDie (Tied Diffusion of Interacting Events) (Paull *et al.*, 2013) uses the concept of heat diffusion to identify novel genes that bridge between relevant starting groups of genes. For example, given a source set of genes that show significant

mutational changes in a specific cancer type and a target set of genes that exhibit significant transcriptional changes in the same context, TieDie (Paull *et al.*, 2013) uses two diffusion processes to find the genes that, given a specific pathway or protein interaction structure, lie in the intersection of the paths of the diffusion processes. The method is not restricted to pairs of processes and can be generalized to multiple starting gene sets. Theoretically, it can also incorporate more general cellular features such as metabolites.

A more general approach is based on Prize-collecting Steiner Tree (PCST) methods, and removes the requirement that all data from one experiment (genetics) lie upstream of the data from another type (gene expression). The PCST-based methods allow for other network topologies. The PCST approach has been applied to biological problems by Dittrich *et al.* (2008), Huang and Fraenkel (2009), and Bailly-Bechet *et al.* (2010). Edges are given positive costs representative of a quantitative measure of the quality of the interactions, while nodes are given positive prizes reflective of the importance and significance of a protein as a hit (Figure 1). The problem is then reduced to identifying a subgraph that balances the minimal cost of included edges and the maximal prize of included nodes. The algorithm can be implemented using an efficient message-passing methodology (Bailly-Bechet *et al.*, 2010a) or a linear programming approach (Dittrich *et al.*, 2008; Huang and Fraenkel, 2009). The Prize-collecting Steiner Forest (Tuncbag

Figure 1 Overview of prize-collecting Steiner approaches.

et al., 2013) represents a generalization of these approaches that allows for discovery of several unconnected networks. In addition, Gitter *et al.* (2014) have introduced a method for simultaneously analyzing multiple patients with similar, but distinct data.

Distinguishing Proteins and Genes

Almost all of the methods we described above use a single node to represent both a protein and the gene that encodes it. All data about the gene and protein are then localized to the same place in the network, regardless of what they represent. These data could include a change in the level of the mRNA encoding the gene, the level of the protein, a point mutation, a posttranslational modification, etc. Similarly, many of the methods also treat all interaction types as equivalent. An edge may represent a direct, physical interaction or a highly indirect connection, such as co-expression or a genetic interaction. Initially, these choices were a matter of necessity.

When microarrays were the only high-throughput method for measuring molecular activity, it was reasonable to treat these data as a proxy for protein levels. However, with the advent of high-throughput proteomic methods we can directly ask whether mRNA levels predict protein levels. Initial analyses using microarray data showed that the correlation existed, but was weak (Tuncbag *et al.*, 2013). In fact, for any particular level of mRNA expression, there was a 1000-fold range in protein levels. Subsequent RNA-Seq analyses have demonstrated that this technique is only marginally better at predicting protein levels; the best correlation coefficient in a recent study was only 0.54 (Ning *et al.*, 2012).

Given the poor correlation between mRNA expression and proteomic data, mapping all biological entities to the same place in the interaction network is far from ideal. There are several approaches for dealing with this problem.

In the network algorithms published by our group (Huang and Fraenkel, 2009; Tuncbag *et al.*, 2013; Gitter *et al.*, 2014) (including ResponseNet and PCST described above), we separate mRNAs and the proteins they encode by allocating a different node for each one. Then protein–protein interactions can only occur between protein nodes, while protein–DNA interactions connect mRNA nodes to the protein network. The protein–DNA interactions can be either derived directly from ChIP-chip or ChIP-Seq experiments that measure such interactions (Yu *et al.*, 2009; MacIsaac *et al.*, 2010) or computationally from epigenomic and sequencing data (Huang and Fraenkel, 2009).

The PARADIGM algorithm (Vaske *et al.*, 2010) introduces a much more general alternative strategy. They encode previously characterized pathway topology in the network where individual cellular states or identities, such as a given gene, mRNA, or protein are represented as variables, and the interactions and relationships (pathway structure) that relate these states or identities are represented as factors. In this approach, for example, a gene is connected to its encoded protein by a factor node that can explicitly represent any known regulation of translation. Given enough prior data regarding regulatory steps, a factor graph could be used to describe arbitrarily complex biological processes with separate nodes for each type of data. However, current datasets are not rich enough to allow

the *de novo* discovery of the parameters for a complicated factor graph in the absence of such prior knowledge.

Outlook

What can we learn from modeling biological networks? The approaches we reviewed have already proved very useful in finding connections among diverse data. One of the great outstanding challenges will be to use these networks to make specific predictions regarding these systems in new settings. Transitioning from network models that explain existing data to ones that predict the results of future experiments will be extremely challenging. We expect that progress will depend, in part, on finding increasingly realistic ways of modeling distinct types of data that are faithful to underlying physical structure of true biological networks.

Stochastic Analysis of Nongenetic Cell-to-Cell Heterogeneity

CC Wang and KA Janes, University of Virginia, Charlottesville, VA, USA

© 2016 Elsevier Inc. All rights reserved.

Glossary

Fluorescence-activated cell sorting (FACS) A form of flow cytometry for sorting cell subpopulations into multiple containers based upon the light scattering and fluorescent characteristics in each cells.

Intermembrane space (IMS) The region between the inner and outer membrane of a mitochondrion.

Laser capture microdissection (LCM) A method for isolating specific cells of interest from microscopic regions of tissue/cells.

Mitochondrial outer membrane permeabilization (MOMP) MOMP is induced by intrinsic apoptotic

signaling and allows for release of pro-death factors into the cytosol.

Nuclear export signal (NES) An amino acid sequence that tags a protein for export from the cell nucleus to cytoplasm by nuclear transport.

Nuclear localization signal (NLS) An amino acid sequence that tags a protein for import into the cell nucleus by nuclear transport.

Pleckstrin homology (PH) domain A protein domain that can bind phosphatidylinositol lipids and plays a role in recruiting proteins to cell membrane.

Introduction

Genetically identical cells in a homogeneous environment can exhibit a range of phenotypes. The sources of nongenetic heterogeneity can be stochastic through random fluctuations inside the cells, or they can be regulated through feedback mechanisms. Cell-to-cell heterogeneity causes cells to vary in their responsiveness to stimuli and has profound effects on their phenotypes (Magee *et al.*, 2012; Marusyk *et al.*, 2012).

Phenotypic heterogeneity arises in cell fates ranging from pluripotent stem cells (Buganim *et al.*, 2012; Hanna *et al.*, 2009; Takahashi and Yamanaka, 2006) to apoptosis (Spencer *et al.*, 2009). Such functional heterogeneity is involved in nondeterministic cell fates during development (Losick and Desplan, 2008) and is thought to be suppressed in mature tissues. In cancer, however, nongenetic heterogeneity has been widely described (Quintana *et al.*, 2008; Visvader and Lindeman, 2008). Cell-to-cell heterogeneity results in non-uniform responses to anticancer agents and fractional killing, creating a major obstacle for cancer therapy (Fallahi-Sichani *et al.*, 2013; Sharma *et al.*, 2010).

The dynamics of cell responses further increases the complexity of cell-to-cell heterogeneity. Stochastic state transitions are frequently encountered in both transformed and non-transformed cells (Chaffer *et al.*, 2011; Gupta *et al.*, 2011; Wang *et al.*, 2014). The ability to transition reversibly between states establishes a steady-state distribution of heterogeneity in cancer cell populations (Gupta *et al.*, 2011). During the process of tumor metastasis, disseminated cells switch between epithelial and more invasive states (Mani *et al.*, 2008). These studies suggest that intra-tumor heterogeneity cannot be completely explained by biochemical noise and might in part reflect cellular state transitions that are regulated.

The transition between distinct states is mediated by the regulation of gene expression (Chaffer *et al.*, 2013; Wang *et al.*, 2014). Several studies suggest that activation of state-switching programs is triggered by contextual signals. For example, transforming growth factor beta (TGF β) signaling has been

observed to trigger the oscillation between gene expression programs in basal-like epithelial cells (Wang *et al.*, 2014) to establish a tumor-propagating state (Shipitsin *et al.*, 2007). TGF β -driven cell-state plasticity in basal breast cancer was achieved through the activity of a key transcription regulator (Chaffer *et al.*, 2013). Signaling and transcription mechanisms may also work together to create feedback loops that result in dynamic regulatory heterogeneity (Ashall *et al.*, 2009; Hoffmann *et al.*, 2002; Tay *et al.*, 2010; Wang *et al.*, 2014).

Cell-to-cell heterogeneity exists at multiple levels, including gene expression states, signal-transduction states, and cellular phenotypes. In this article, we discuss variability that occurs in signal transduction and gene expression. We also review the experimental tools used for measuring the molecular processes underlying the observed heterogeneity. Finally, we will discuss recent systems biology approaches that connect different levels of variability and their role in cell-fate decisions.

Cell Signaling

Cells sense extracellular signals and transfer information to make appropriate decisions. These signal-transduction networks are subject to various sources of noise. In addition, cellular function is dynamic, and the observed heterogeneity may also reflect asynchronous transmission of signals in the overall population. Here, we discuss the cell-to-cell heterogeneities in signaling that arise from differences in molecular states among cells and the stochastic events or unsynchronized dynamics of the relevant signaling networks.

Molecular-State Differences

Diverse states among cells – including the concentration levels, subcellular locations, and activities of key signal regulators – can generate a broad distribution of signaling responses. For example, in mammary epithelial cells, Akt activation is bimodal in response to epidermal growth factor (EGF)

stimulation (Yuan *et al.*, 2011). This on-or-off heterogeneity correlates with the abundance of phosphoinositide 3-kinase (PI3K). Only cells with high levels of PI3K protein can activate Akt. Variable concentrations of upstream signal proteins, including PI3K, PTEN, and cMet, are also responsible for the heterogeneous activation of Akt in response to hepatocyte growth factor (HGF) (Meyer *et al.*, 2012). The variable concentration of signaling components is one of the key determinants for the heterogeneous PI3K signaling response.

Another important pathway usually misregulated in human cancers is the Ras/extracellular signal-regulated kinase (ERK) pathway. The kinetics of ERK phosphorylation and nuclear translocation govern different cellular outcomes (Ahmed *et al.*, 2014; Marshall, 1995). Cell-to-cell heterogeneity is observed in both signal strength and dynamics of the Ras/ERK pathway. For example, ERK2 shows variability in its basal nuclear levels (Cohen-Saidon *et al.*, 2009). Upon EGF stimulation, the relative increase in nuclear ERK2 level is proportional to the basal level in each cell (Cohen-Saidon *et al.*, 2009). ERK can be activated in discrete, asynchronous pulses under conditions of steady-state EGF stimulation spanning the physiological range (Albeck *et al.*, 2013; Shankaran *et al.*, 2009). The dynamics and amplitude of ERK signaling are determined by the activity of upstream signaling proteins, EGFR and MEK, respectively (Albeck *et al.*, 2013). This suggests the thresholds of signaling protein activity is different between cells, by which Ras/ERK pathway exhibits strong variability and influences the cell-fate decision to undergo proliferation.

Cell-to-cell variability is also observed in ligand-mediated cell death. For example, tumor necrosis factor (TNF)-related apoptosis-inducing ligand (TRAIL) initiates apoptosis in mammalian cells with a pronounced temporal variability (Spencer *et al.*, 2009). Some cells die within minutes, while others die several hours later. The time-to-death is highly correlated within newly born sister cells whose behavior and total protein levels are synchronized. The primary determinant of variability in time-to-death was associated with the rate of caspase-mediated activation of BID (Albeck *et al.*, 2008; Spencer *et al.*, 2009). The correlated apoptosis of sister cells diverges as new proteins are produced, suggesting the relationship between signal-induced apoptosis and total protein levels. A follow-on study related to this work showed that the cell subpopulation surviving the TRAIL stimulus regenerates the sensitivity and death-time distribution of the parental population upon growth for several days in the absence of TRAIL (Flusberg *et al.*, 2013). This suggests that some cell-state variability arises from stochastic fluctuations in mRNA and protein production (Munsky *et al.*, 2012).

Stochastic Events in Signaling

Signal transduction is a complex process of protein interactions that occur after environmental stimulation. Many of these steps are transient and rely on relatively low-affinity interactions between binding partners (Pawson and Nash, 2003; Zheng *et al.*, 2013). The human interactome contains approximately 130 000 binary interactions, most of which are uncharacterized (Venkatesan *et al.*, 2009). Specific interactions between recognition domains within a signaling pathway

must therefore compete against the bulk of nonspecific interactions. Stochastic fluctuations in cell signaling thus could be partly attributed to the lack of sufficient specificity in protein-protein interactions (Ladbury and Arold, 2012).

Stochastic fluctuations in signaling cause a constant 'background noise' in the network. The background can consist of low signals through random transient protein interactions. A functional signal must prevail above this noise threshold. Background noise therefore limits the information capacity of signaling pathways. Information captured by individual pathways induced by TNF (Cheong *et al.*, 2011), platelet-derived growth factor (PDGF) (Cheong *et al.*, 2011), and EGF (Cohen-Saidon *et al.*, 2009) has been reported to be limited by noise. Although the noise from nonspecific interaction is unavoidable, negative feedback loops are able to reduce the amount of noise that corrupts a signal (Cheong *et al.*, 2011). In addition, feedback loops in signaling networks may serve as built-in reset mechanisms that preserve the dynamic capabilities for future stimuli (Yu *et al.*, 2008). Given that signaling changes are a greater determinant of cellular outcomes than signal strength (Janes *et al.*, 2008), signaling networks with higher-level connections, such as crosstalk and feedback loops (Cirit *et al.*, 2010; Wang *et al.*, 2009), maybe more effective than single pathways at signal transfer. The analysis of noise that has been applied to single pathways can be extended to different network structures to determine what signaling architectures can function reliably despite noise.

Signaling Oscillations

Signaling networks are now often viewed as a self-regulating system of interlinked feedback loops (Cirit *et al.*, 2010; Sachs *et al.*, 2005; Wang *et al.*, 2009). Feedback loops can generate nonlinear dynamics and oscillation in cell signaling. Oscillations have been observed in key signal regulators, including intracellular Ca^{2+} (Dolmetsch *et al.*, 1997), surface receptors Notch (McMahon *et al.*, 2008) and TGFBR3 (Wang *et al.*, 2014), protein kinase ERK (Shankaran *et al.*, 2009), and transcription factors p53 (Lahav *et al.*, 2004), STAT3 (Yoshiura *et al.*, 2007), Smad2 (Wang *et al.*, 2014), and NF- κ B (Nelson *et al.*, 2004). Since cells do not oscillate in synchrony, the asynchronous population exhibits cell-to-cell variability.

TNF α treatment induces NF- κ B nuclear translocation. NF- κ B regulates transcription of genes, including several that can feed back to regulate NF- κ B localization (Hoffmann and Baltimore, 2006). One of these feedbacks is mediated by I κ B α , which upon binding to NF- κ B in the nucleus shuttles NF- κ B back to the cytoplasm (Nelson *et al.*, 2004). Earlier population-level studies demonstrated a temporal profile of NF- κ B activity (Cheong *et al.*, 2006). Increasing the concentration of TNF α leads to a shortened delay in NF- κ B nuclear translocation. Single-cell studies, however, showed synchronous cycles of NF- κ B translocation (Ashall *et al.*, 2009). Timed fluctuations in TNF α resulted in differences in amplitude in NF- κ B translocation. Recent studies that measure NF- κ B activities in thousands of live cells revealed that transcriptional activity is heterogeneous at lower TNF doses (Tay *et al.*, 2010). Cells process fold change signals to create digital outputs for early gene expression (Lee *et al.*, 2014). Signal heterogeneity observed in fixed cells may not only be caused by intrinsic

stochasticity, but also by regulatory elements in the signaling networks.

Oscillations in cell signaling have an important role in cell function (Cai *et al.*, 2008; Purvis and Lahav, 2013). Recent studies in human epithelial cells reveal that TGFBR3 activity is built into a signaling-transcriptional circuit consisting of multiple negative feedback loops (Wang *et al.*, 2014). When the circuit is excited by TGF β family ligands, TGF β signaling displays a damped oscillation and cells transition spontaneously between gene expression states. This dynamic oscillation is important for normal morphogenesis in 3D acini and may be engaged by breast premalignancies. Strong links between signal oscillation and gene expression suggest the important roles of signaling feedback loops in regulating nongenetic heterogeneity.

Variability in Gene Expression

Transcriptome-wide studies of cell-to-cell variability at the mRNA or protein level in *Saccharomyces cerevisiae* reveal that variability in protein expression is dominated by the stochastic production and destructions of mRNA (Bar-Even *et al.*, 2006; Newman *et al.*, 2006). Such transcriptional variability could reflect the upstream influence from signaling pathways described above, as well as intrinsic stochasticity in transcriptional programs (Elowitz *et al.*, 2002). Intrinsic stochasticity could be attributed to two elements. The first is the probabilistic synthesis and decay of mRNA transcripts, because of the small copy numbers of many mRNA species (Suter *et al.*, 2011). Second, mRNAs are synthesized in short but intense bursts of transcription. This transcription burst is intrinsically random (Raj *et al.*, 2006) and is controlled by stochastic transitions between different regulatory states (Singh *et al.*, 2012). Bursts are correlated between genes that are located proximally (Raj *et al.*, 2006), suggesting that random events of chromatin opening and closing may be responsible for switching between transcriptionally active and inactive states.

Given the discrete nature of transcription, it is clear that assessing gene expression in single cells is critical to gain a better understanding of cell-to-cell variability. With the development of single-cell transcriptomics (Deng *et al.*, 2014; Jaitin *et al.*, 2014; Picelli *et al.*, 2014; Shalek *et al.*, 2013), studies of gene expression and regulation in single cells will improve inferences of gene-regulatory networks (Kim *et al.*, 2009; Wang *et al.*, 2014).

Single-Cell Analysis

Observing cell-to-cell heterogeneity requires the ability to measure biological readouts at the level of single cells. Variability occurs at many levels that vary across timescales. When cells detect extracellular signals, the early response in cell signaling can occur within seconds or minutes. The consequent gene expression changes lead to new cell phenotypes in hours to days. Cell signaling and transcription are highly dynamic and involve many elements, posing a major challenge to quantify them. Single-cell analysis has emerged as an active area of research now that new technologies have made it

possible to measure single-cell processes at the systems level. Here, we review a handful of the experimental tools that have been used to measure different biochemical events of cell signaling and transcription in single cells.

Single-Cell Transcriptomics

Single-cell transcriptomics has emerged as a potential technology to explore gene expression heterogeneity (Eberwine *et al.*, 2014; Sandberg, 2014). Advances in single-cell isolation as well as whole-transcriptome amplification and analysis platforms, such as microarrays and more recently RNA sequencing (RNA-Seq), have paved the way for high-resolution analysis.

Technical limitations

Single-cell transcriptomics relies on the reverse transcription of RNA to complementary DNA (cDNA) and subsequent amplification by polymerase chain reaction (PCR) or *in vitro* transcription (IVT) before deep analysis. A human cell contains ~ 1 pg of mRNA. 85% of transcripts have fewer than 100 copies per cell and many of them are present at only 5–20 copies per cell (Macaulay and Voet, 2014). Reverse transcription, the initial step of most RNA analysis, is likely one of the limiting factors in quantification of single-cell transcripts. It is estimated that on average only 5–25% of all RNA molecules are converted into amplifiable cDNA, while transcripts with 10 copies or more per cell were reliably quantified (Islam *et al.*, 2012).

Microarrays and RNA-Seq require nanogram quantities of DNA as the starting material. Whole-transcriptome amplification still introduces biases in representation by favoring high-abundance transcripts. The biases originate from the need for high amplification from the small amount of RNA available from single cells. Microfluidics-based detection platforms seek to improve sensitivity by reducing reagent volumes to increase effective concentrations (Warren *et al.*, 2006). However, they still require exponential preamplification to achieve single-cell sensitivity of low-abundance targets (Dalerba *et al.*, 2011). PCR-based amplification methods have the potential for nonlinear amplification, resulting in the distortion of the relative abundance of transcripts (Raj and van Oudenaarden, 2009). IVT amplification may arguably avoid such problem through linear amplification (Eberwine *et al.*, 1992). However, IVT imposes a minimal starting amount of ~ 400 pg of RNA for sufficient yield and a new strategy, such as barcoding and pooling samples (Hashimshony *et al.*, 2012), may need to be applied in the procedure to overcome this limitation.

A unique strategy, termed stochastic profiling, has been reported to remove the bottleneck of small amounts of input material (Janes *et al.*, 2010; Wang and Janes, 2013). Stochastic profiling uses not a single-cell as the starting material but rather small pools of 10 cells randomly selected from a population. Fluctuations in the 10-cell averages are then analyzed statistically to reveal heterogeneously regulated transcripts and transcriptional programs. Additional statistical and bioinformatic analyses allow for the quantification of cell-to-cell heterogeneity in gene expression (Bajikar *et al.*, 2014).

Finally, single-cell transcriptomics requires the isolation of RNA from the single cells. Most high-throughput cell isolating

tools to date require cells in suspension. Spatial information is lost when dissociating cells from tissues or cultures using flow cytometry and microfluidic platform. Spatially defined single cells can be acquired through laser capture microdissection (LCM), which has also been used to isolate transcripts in single cells (Tietjen *et al.*, 2003, 2005). For dense tissue, LCM may introduce higher levels of contamination compared to flow cytometry-based methods (Okaty *et al.*, 2011). However, the advantages of *in situ* profiling are often more important than the contamination, which can be controlled.

Near-term challenges

There remains a need for further development to boost single-cell RNA detection. Lowering RNA losses and enhancing the efficiencies of reverse transcription before amplification are important directions to pursue for improving RNA detection in single cells (Islam *et al.*, 2012; Picelli *et al.*, 2013). Simultaneous detection of polyadenylated RNA and regulatory RNAs is also an important area for future development.

There is also room to improve the process of dissociation of individual cells (Shapiro *et al.*, 2013). Individual cells can be isolated using fluorescence-activated cell sorting (FACS). FACS-based sorting is a robust method that has benefited from decades of refinement. However, standard FACS needs a large pool of cells as starting material, which affects its application to low-abundance samples, such as circulating tumor cells purified from blood. Microfluidics can help with these types of applications (Karabacak *et al.*, 2014; Yu *et al.*, 2013). However, for solid tissues, neither method is satisfactory, because knowledge of the spatial location is lost. LCM can be used to cut cells from fixed tissues or cryosections. Using LCM-based methods, the spatial information of a sampled cell is retained. However, it is a labor-intensive, low-throughput tool. In addition, it is difficult to capture an entire cell without collecting collateral material from neighboring cells. Thus, the improvement of cell picking methods will be valuable for single-cell analysis.

Single-Cell Signaling Events

With the ongoing development of single-cell approaches, quantitative analysis of single-cell transcriptomics is becoming possible. Another layer of biological complexity lies in how cells with different gene expression states respond to their environment differently. Understanding the relationship between gene expression and cell signaling in single cells remains an unfulfilled goal for single-cell studies. Studying the heterogeneity in cell signaling at the single-cell level requires the tracking spatiotemporal dynamics of signaling proteins through their localization, activity, and interactions with other proteins.

Measuring protein translocation

The intracellular localization and translocation of proteins are critically tied to protein function and activation state (Andjelkovic *et al.*, 1997; Kluck *et al.*, 1997). An example is the interaction of Akt and 3-phosphoinositide dependent protein kinase-1 (PDK1). Both Akt and PDK1 bear pleckstrin homology (PH) domains that recognize the product of PI3K,

phosphatidylinositol 3,4,5-trisphosphate (PIP3) (Alessi *et al.*, 1997; Franke *et al.*, 1997; Weiger *et al.*, 2009). Akt and PDK1 accumulate at the membrane, PDK1 activates Akt by phosphorylation, and then Akt transfers the signal downstream. Thus, the translocation of signaling proteins or their recognition domains to subcellular compartments has widely served as the proxy of pathway activity dynamics (Bandara *et al.*, 2009; Galic *et al.*, 2012; Wang *et al.*, 2014; Weiger *et al.*, 2009; Yang *et al.*, 2012).

Most of the membrane-translocation reporters have been created as fusion proteins with a fluorescent probe and a lipid-binding domain. PH domains are the most abundant lipid-binding domains in eukaryotes and bind specifically to PIP3, PI(4,5)P2, or PI(3,4)P2 (Lemmon, 2007). These domains possess different phosphoinositide specificities and affinities and show strikingly different membrane recruitment kinetics *in vitro* and *in vivo* (Manna *et al.*, 2007). For example, Btk-PH shows genuine PIP3 specificity *in vitro* (Manna *et al.*, 2007), but does not catch the rapid accumulation of local PIP3 in single cells (Varnai *et al.*, 1999). In mammalian cells, the Akt-PH domain has served as the best reporter for local PIP3 production (Servant *et al.*, 2000). Although the Akt-PH domain may also bind to PI(3,4)P2, it clearly polarizes during chemoattractant receptor signaling. The localization of many binding domains is more dependent on protein-protein interactions at the plasma membrane than lipid-binding per se (Manna *et al.*, 2007). Thus, localization kinetics is as important as the lipid-binding specificities when designing membrane-translocation reporters.

Nuclear translocation of many transcription factors is a key step for cellular signaling to elicit changes in gene expression. The dynamic movement of fluorescently labeled signaling proteins can be mentored at the single-cell level by time-lapse microscopy. Live-cell imaging approaches have been used to reveal the dynamic regulation of transcription factors such as NF- κ B (Nelson *et al.*, 2004), p53 (Lahav *et al.*, 2004), STATs (McBride and Reich, 2003), and Smads (Wang *et al.*, 2014; Warmflash *et al.*, 2012), and these reporters all showed heterogeneous translocation dynamics in single cells.

Retention or release of proteins from the mitochondria has been used as a terminal indicator of apoptosis in single cells (Albeck *et al.*, 2008; Spencer *et al.*, 2009). The intermembrane space (IMS) reporter protein (IMS-RP) was created by fusing a fluorescent protein to the mitochondrial import sequence of the mitochondrial protein Smac (Albeck *et al.*, 2008; Du *et al.*, 2000). During apoptosis-associated mitochondrial outer membrane permeabilization (MOMP), IMS-RP is released from the IMS into the cytosol. IMS-RP does not contain the inhibitor of apoptosis protein (IAP) binding motif and is biochemically neutral. IMS-RP has been used to analyze the drug-induced apoptosis in human breast and pancreatic cancer cells (Earley *et al.*, 2012). The use of IMS-RP will allow visualization of heterogeneous drug responses and could be useful for examining the origins of drug resistance.

Measuring protein interactions and activity

Direct protein interaction is often evaluated by using Förster resonance energy transfer (FRET). FRET utilizes two fluorophores, a donor and an acceptor, of which the donor emission spectrum overlaps with the acceptor absorption spectrum.

If the two fluorophores are in close proximity (1–10 nm), excitation of donor results in acceptor emission due to the overlap in spectra that allows resonance energy transfer between two probes. FRET is now widely applied in cell signaling studies to detect protein–protein interactions. Advances in using three fluorescent proteins enable the study of higher-order protein complexes. In trimeric complexes, cyan fluorescent protein (CFP) is the donor for yellow fluorescent protein (YFP); subsequently, YFP can act as the donor of red fluorescent protein (RFP). 3-FRET has been applied to the analysis of three-protein interactions (Galperin *et al.*, 2004) and trimerization of TNF receptor-associated factor 2 (TRAF2) in living cells (He *et al.*, 2005).

FRET-based methods have been expanded to monitor the dynamics of kinase activity by combining a peptide substrate and a phosphopeptide recognition module. For example, FRET sensors of ERK activity have been applied in living cells (Harvey *et al.*, 2008; Tomida *et al.*, 2012). ERK activity sensors include a substrate phosphorylation peptide, an ERK docking domain, and a phospho-binding WW domain. ERK activation leads to phosphorylation of the substrates and subsequent binding by WW domain. The resulting conformational rearrangement triggers a change in FRET between the donor and acceptor. The extent and duration of ERK activity were determined by FRET in response to complex stimuli (Tomida *et al.*, 2012). The reporter of kinase activity has been used in conjunction with other reporters to link complex ERK dynamics to S phase entry (Albeck *et al.*, 2013). However, there are several limitations of FRET-based methods for their widespread adoption. For example, FRET has relatively low signal-to-noise ratio. FRET requires multiple fluorescent proteins and thus limits the number of the targets that can be observed simultaneously. Besides, the closed conformation of the FRET sensor is highly stable and cannot be reset by the phosphatases (Komatsu *et al.*, 2011). These restrict FRET from accurately representing the dynamic regulation of kinase activities in the same live cells.

A new strategy to design single-cell reporters for kinase activity is based on the concept of converting phosphorylation into nucleo-cytoplasmic translocation (Regot *et al.*, 2014; Spencer *et al.*, 2013). A recently reported mammalian cyclin-dependent kinase 2 (CDK2) reporter includes YFP mVenus fused to amino acids 994–1087 of human DNA helicase B (DHB) that contains four CDK consensus phosphorylation sites, a nuclear localization signal (NLS), and a nuclear export signal (NES) (Spencer *et al.*, 2013). CDK2 reporter localizes to the nucleus in newly born cells. DHB is specifically phosphorylated by CDK2 whose activity is upregulated in G1 before DNA replication (Massague, 2004). CDK2 reporter then translocates out of the nucleus and exhibits cytosolic localization at the end of G2. The cytoplasmic-to-nuclear ratio of the reporter is used as the readout of CDK2 activity. This strategy has recently been generalized to kinase translocation reporters (KTRs) of enzymatic activity (Regot *et al.*, 2014). A KTR includes a docking site and phosphorylation site of the target kinase, a bipartite NLS, an NES, and a single fluorescent protein. KTR can be applied to multiple types of kinases simply with minimal optimization and has been successful for three classes of kinases (MAPKs, CDKs, and AGC kinases) (Regot *et al.*, 2014; Spencer *et al.*, 2013). These new techniques

open the possibility of analyzing a wide range of kinase-mediated processes in individual cells.

Despite these advances, live-cell imaging techniques are still limited by several drawbacks. Fluorescence microscopy has the limited number of color channels that can be viewed simultaneously without spectral overlap. It remains an experimental challenge to use three to four fluorescent activity reporters simultaneously in live cells (Machacek *et al.*, 2009; Regot *et al.*, 2014). Overexpression of certain reporters may create artifacts related to competition with endogenous substrates (Ahmed *et al.*, 2014). Moreover, plasmid copy number can vary per cell, causing heterogeneity that does not reflect true intracellular events. Knockin of fluorescent reporters into endogenous loci by using CRISPR/Cas (Yang *et al.*, 2013) or gene tagging (Sigal *et al.*, 2006) should alleviate some of these concerns, although sensitivity of detection could then become an issue. In addition, primary cells remain a major challenge for all of these techniques (Saucerman *et al.*, 2006; Yang *et al.*, 2014). End-point fixed-cell methods with flow cytometry or microscopy may provide the flexibility to measure multiple phospho-signals and regulatory proteins together when time-evolution is not critical. The fusion of different techniques holds the greatest potential to decipher the spatial and temporal interplay of multiple signaling activities within single cells (Albeck *et al.*, 2008, 2013).

Modeling and Analysis of Stochastic Data

Modeling and Analysis of Single-Cell Signaling Networks

For population-averaged data, ordinary differential equation (ODE)-based models are powerful tools to integrate mechanistic information and describe signaling kinetics (Aldridge *et al.*, 2006). ODE models have also been used with single-cell data from live-cell microscopy and flow cytometry to investigate cell-to-cell variability in apoptotic signals (Spencer *et al.*, 2009). However, deterministic ODE models do not always represent signaling at a single-cell level, where stochasticity may affect the probability of signaling and molecular states (Altschuler and Wu, 2010; Cheong *et al.*, 2010).

Using Bayes probability theorem, Bayesian networks are suitable for learning network connections from a distribution of single-cell events. The ability to express probabilistic relationships among network variables makes Bayesian approaches valuable for integrating single-cell data (Kolitz and Lauffenburger, 2012). Bayesian networks have inferred causal interactions in a kinase-signaling network by using the phospho-protein levels in single cells (Sachs *et al.*, 2005). These approaches enable the inference of networks in which not all molecules are measured (Sachs *et al.*, 2009). A main drawback of Bayesian networks is that they need a lot of data, usually hundreds to thousands of observations. In addition, the complexity of possible networks that must be searched grows super-exponentially with the number of nodes in the networks, requiring high-performance computing for all but the smallest networks.

A separate challenge for single-cell signaling is the reliability of transmitting signals. Here, information theory has been employed to study the ability of single cells to transfer

environmental information in the presence of noise within a signaling network. For example, Cheong *et al.* used mutual information between intracellular relay points to evaluate the fidelity of information flow along the NF- κ B pathway in single cells during TNF α stimulation (Cheong *et al.*, 2011). It was suggested that individual pathways could only discriminate between the presence and absence of TNF α . This relatively low transmission capability was attributed to an information bottleneck around the receptors. The authors also suggested that one role of negative feedback in signaling networks is to improve the information-carrying capacity. Modeling the information flow in networks may need to include measures of the transfer function between nodes (Toettcher *et al.*, 2013).

The single-cell techniques discussed earlier are limited by the number of markers that can be observed in parallel, but methods are being rapidly developed to address this problem. By combining mass spectroscopy and flow cytometry, mass cytometry allows quantitative monitoring of a large number of parameters simultaneously in single cells (Bendall *et al.*, 2011). The increasing multidimensional types of data require specific visualization and analysis methods. An algorithm, termed Spanning-tree progression analysis of density-normalized events (SPADE), was created to cluster cell subsets in multidimensional space and then reduce them to a 2-D representation tree structure (Qiu *et al.*, 2011). In addition, the recently developed viSNE algorithm has allowed high-dimensional data to be compressed into a 2-D map that discriminates cellular subpopulations without the loss of single-cell resolution (Amir *et al.*, 2013). These approaches are unsupervised and prior knowledge of the system is not required. They are thus suitable for navigating complicated, interconnected signaling networks in search of hypotheses.

Modeling Single-Cell Transcriptomic Data

Nongenetic variability in gene expression may result from both population heterogeneity and temporal fluctuations (Huang, 2009). Temporal fluctuations are assumed to be regulated by the stochastic synthesis and degradation of individual transcripts, while population heterogeneity may be due to the stable differences among cells. It is difficult to distinguish one from the other in experimental data. However, if temporal fluctuations in gene expression are fast (Yu *et al.*, 2006), they may satisfy the assumption of ergodic theory, which states that the temporal fluctuation of an individual cell can be estimated by measuring the population at one time point (Eckmann and Ruelle, 1985). Thus, a single snapshot of cells in the same population can be used to infer the temporal fluctuations in individual cells.

Experimental observations of single-cell gene expression are usually noisy. Owing to low amounts of input material, true biological variability and technical noise are often at comparable levels (Brennecke *et al.*, 2013). The relative amount or the presence/absence of individual transcripts may be dominated by technical error. In addition, the transcript numbers of 'housekeeping' genes, such as *GAPDH* and *POLR2A*, show considerable variability at the single-cell level (McDavid *et al.*, 2013). Standard methods of data normalization based on such genes will result in quantitative artifacts.

Addressing these statistical and analytical challenges in single-cell data is critical for making appropriate interpretations.

A number of approaches for modeling of single-cell transcriptomic data have been reported including the use of external RNA controls as a reference material (Brennecke *et al.*, 2013; Grun *et al.*, 2014; Kharchenko *et al.*, 2014), Bayesian statistics of differential gene expression (Kharchenko *et al.*, 2014), or unique molecular identifier barcodes for individual transcripts (Grun *et al.*, 2014). It has been estimated by these models that approximately half of the reads may be contributed by technical noise (Brennecke *et al.*, 2013). Thus, challenges remain for analyzing stochastic single-cell data in a reliable way.

An alternative approach with less-stringent sample requirement is to analyze multiple sets of small samples, rather than single-cell samples. Probability theory and random sampling have been used together to survey the gene expression programs that are significantly heterogeneous among individual cells (Janes *et al.*, 2010; Wang and Janes, 2013). Using 15–20 random samples of 10-cell averages allows the resulting distributions to distinguish cell-to-cell variations by statistical hypothesis testing. Moreover, these stochastic-profiling experiments are quantitative because the 10-fold increase in input material allows for more-accurate measurements compared to single-cell data. Recently, it has been shown that mathematically deconvolving measurements from small groups of cells can quantify single-cell regulatory heterogeneities while avoiding measurement noise (Bajikar *et al.*, 2014). It remains unclear whether noisy one-cell data or robust 10-cell data will ultimately be more useful for uncovering new single-cell biology.

Connecting Heterogeneity at Multiple Levels

A primary goal of studying cell-to-cell heterogeneity is the potential to connect underlying variability with heterogeneous outcomes. Ultimately, this will require combining different methods that quantify gene expression products, signaling activities, and functional responses to link upstream cellular variability to a downstream cell-fate decision (Wang *et al.*, 2012).

Variability in gene expression can give rise to phenotypic heterogeneity. Gene expression begins with transcription, which implies that the fluctuation of mRNA synthesis may propagate to the downstream protein pool. However, in metazoan development, such fluctuation is suppressed and cell fate is highly controlled by the network architecture. In *Caenorhabditis elegans*, mutations to components of a developmental network lead to large variations in the expression of downstream genes (Raj *et al.*, 2010). These variations were thresholded by the organism to give rise to a bimodal expression pattern of key regulatory genes. This suggests the intrinsic mechanisms exist to buffer the stochastic fluctuations in core networks.

Variability in signaling has also been shown to be able to generate subpopulations with distinct cell fates. Many growth factors can induce multiple pathways such as PI3K and Ras pathways. Uniform nerve growth factor (NGF) or EGF stimuli have been found to cause cell-to-cell variability in pAkt and

pERK activation in PC12 cells (Chen *et al.*, 2012). The combined levels of pERK and pAkt define a cell's propensity to undergo proliferation versus differentiation. Thus, both variable signaling and gene expression can be mapped to heterogeneous phenotypes.

Gene expression mediated by viral transduction is also subject to cell-to-cell variability. These variations arise from the stochastic events intrinsic to gene expression, which can be exploited for the analysis of signaling dynamics. This approach has been used to map the biphasic E2F1 response to variability in MYC (Wong *et al.*, 2011). The paradox that MYC can mediate growth signals and trigger growth arrest may be reconciled by taking into account the differing amounts of MYC present in cells.

Conclusion

In this article, we have discussed various levels of cell-to-cell heterogeneity, which create variability in biomolecules that contribute to heterogeneous phenotypes. Cell-to-cell heterogeneity may provide an inherent mechanism to diversify the population-level response to environmental cues. Cells might exploit this mechanism to adapt to external stimuli. Our understanding of heterogeneity will continue to improve as new tools are developed to interrogate the cell and molecular biology that underlies it.

Protein phosphorylation is an abundant posttranslational modification that functions as an important signaling cue. The balance between protein kinase and phosphatase activity mediates the dynamics of phosphorylation to transmit information flow, ultimately directing the activity, localization, and function of signaling effectors. Notably, disequilibrium in the phosphorylation–dephosphorylation balancing act can have severe repercussions, and is a major contributing factor to the manifestation of pathologies such as inflammatory diseases, diabetes, neurodegenerative diseases, metabolic disorders, and cancers. Assigning individual protein phosphorylation events to their cognate kinases and phosphatases is key to understanding the organization and dynamics of signaling networks. While advances in mass spectrometry have facilitated the identification of phosphorylation, the protein kinase(s) or phosphatase(s) responsible for regulating any particular phosphorylation event in most cases is unknown. Moreover, distinguishing functional from spurious phosphorylation remains a significant hurdle to mapping signaling pathways and information processing (Lienhard, 2008). The challenge now lies in trying to pinpoint critical phosphorylation events, their cognate kinase(s), the regulatory organization between kinases and phosphatases, and their relevance to organismal physiology.

In recent years, building on the knowledge of genome sequences and technological advances in molecular biology and proteomics, a number of approaches have been developed to systematically identify protein kinase substrates (Figure 1; Boyle and Koleske, 2007; Sopko and Andrews, 2008). For instance, protein and peptide chips have been used extensively to identify protein kinase substrates (Ptacek *et al.*, 2005), protein kinase consensus motifs (Alexander *et al.*, 2011; Huttii *et al.*, 2004; Mok *et al.*, 2010; Songyang *et al.*, 1994; Turk *et al.*, 2006), and those proteins with which protein kinases can associate (Fasolo *et al.*, 2011; Kaushansky *et al.*, 2008). Similarly,

pools of radiolabeled proteins generated from coupled *in vitro* transcription–translation of verified cDNA libraries have served as substrates to screen for targets of recombinant protein kinases (Gao *et al.*, 2000; Lee *et al.*, 2005). Additionally, reverse phase protein microarrays, bearing spotted lysates rather than purified proteins, have been probed with phospho-specific antibodies to identify kinase targets (Gulmann *et al.*, 2009). All these methods rely on interaction between kinase and substrate in an environment lacking cellular context, and the latter method additionally relies on antibody specificity and avidity. Genetically engineered analog-sensitive kinases capable of accepting bulky ATP analogs have enabled the labeling of direct protein kinase targets in cell lysates (Blethrow *et al.*, 2008; Carlson *et al.*, 2011; Dephore *et al.*, 2005; Holt *et al.*, 2009; Ubersax *et al.*, 2003); however, this approach relies on inconsequential mutation of the kinase ATP-binding pocket. Approaches coupling affinity purification with mass spectrometry have proven fruitful in identifying physical protein kinase–substrate interactions (Breitkreutz *et al.*, 2010; Rohila *et al.*, 2009), although this approach, like yeast two hybrid experiments, is hindered by its inability to identify dynamic kinase–substrate interactions. The varying degree of protein kinase activity and inhibitor sensitivity across cancer cell lines and tumors has been revealed with kinase activity assay for kinome profiling (KAYAK) – a multiplexed kinase assay to simultaneously measure protein kinase activity in lysates (Kubota *et al.*, 2009). This assay provides a survey of protein kinase activity and can be used to identify protein kinases responsible for phosphorylation of a given peptide designed *a priori*. Loss-of-function screens have revealed the influence of individual protein kinases on the phenotype of genetically altered cells, to predict epistasis and kinase-substrate relationships (Baldwin *et al.*, 2008; Bommi-Reddy *et al.*, 2008; Fiedler *et al.*, 2009; van Wageningen *et al.*, 2010). In the reciprocal direction, kinase substrates have been successfully

Figure 1 Methods to link phosphorylation with culpable enzymes. Direct targets can be best predicted from the overlap of *in vitro*, *in vivo*, and *in silico* approaches to distinguish kinase and phosphatase substrates.

predicted by examining the viability of a sensitized kinase mutant in the context of target gain-of-function (Sopko *et al.*, 2006). In addition to these experimental approaches, predictions of kinase substrates using computational methods are commonplace. A number of computational resources predicting kinase-specific phosphosites or phospho-binding motifs are available (Tan and Linding, 2009); however, their use is limited due to their over-predictive nature. Unquestionably, matching protein phosphorylation sites with culpable kinases is challenging, due to the limited specificity and number of kinase consensus motifs, and a number of factors including localization, expression, and association with regulatory subunits or scaffolds (Ubersax and Ferrell, 2007). As such, proving a direct link between any potential kinase-target pair still requires a considerable amount of verification. Mass spectrometry continues to develop rapidly in terms of its application to phosphoproteomics (Jünger and Aebersold, 2013). This technology is sensitive enough to capture and measure global phosphoproteome alterations in different genetic scenarios, and serves as a way to monitor altered information flow, using phosphorylation as a proxy. Notably, the increased sensitivity, speed, and dynamic range of peptide identification with current proteomics platforms is providing near comprehensive and reproducible description of simple proteomes and phosphoproteomes, making comparative analyses between genetic variants, for instance wild-type to mutants, accessible (Ahrens *et al.*, 2010; Picotti *et al.*, 2013). Additionally, the application of isobaric labeling strategies has facilitated multiplexing for relative peptide quantification in tissues and whole organisms. While less expansive scale in terms of the number of protein measurements, mass cytometry provides exquisite sensitivity in concurrently measuring dozens of proteins in individual cells (Bendall *et al.*, 2012). This platform, combining inductively coupled plasma mass spectrometry with flow cytometry, currently enables the detection of trace levels of 37, although theoretically 70–100, proteins simultaneously in 500–1000 cells, per second. This eliminates the hassle of obtaining large quantities of starting material, as would be necessary for traditional phosphoproteomic approaches. The application of this technology for phosphoprotein detection however relies on the specificity of metal isotope-tagged phospho-antibodies in fixed cells. Current detection limits are 100 molecules per cell.

In essence, the identification of phosphoproteins altered specifically in genetic contexts where a protein kinase or phosphatase is mutated, removed, or depleted should drive substrate predictions, as well as help assign function to those corresponding kinases and phosphatases. Such types of experiments have been carried out in budding yeast, *Arabidopsis*, and cell culture using mass spectrometry to measure phosphopeptide levels (Bodenmiller *et al.*, 2010; Chen *et al.*, 2010; Gnad *et al.*, 2013; Hilger *et al.*, 2009; Smolka *et al.*, 2007; Umezawa *et al.*, 2013). While large-scale application of this type has been carried out in yeast with kinase and phosphatase knockouts (Bodenmiller *et al.*, 2010), a lack of scalable genetic tools for similar systematic studies has stalled *in vivo* analyses in metazoan systems. Given the recently improved efficacy of RNAi during *Drosophila melanogaster* embryogenesis (Ni *et al.*, 2011) and the relative ease with which one can collect large numbers of staged *D. melanogaster* embryos, we generated a

library of shRNA-based RNAi reagents for analogous quantitative proteomic studies (Sopko *et al.*, 2014). The library accounts for three-quarters of kinase and phosphatase encoding genes in the *D. melanogaster* genome, 95% of which are conserved to human. The smaller genome and hence proteome of *D. melanogaster*, as compared to human, allows for more extensive peptide detection and deeper protein coverage making in *D. melanogaster* more accessible for quantitative studies. Expression in the female in *D. melanogaster* germline of efficient protein kinase and phosphatase-targeting shRNAs permits the generation of eggs depleted of these single gene products. In order to perform a quantitative assessment of all phosphorylated proteins in eggs depleted for specific protein kinases (essentially a phosphorylation signature), we employed isobaric peptide labeling, which enables concurrent quantitation of multiple shRNA-expressing genotypes relative to one another and a common control. As a proof of principle, we carried out phosphoproteomic profiling on embryos depleted of 19 different *D. melanogaster* protein kinases for the purpose of systematically linking protein phosphosites with these maternally inherited kinases. To date, in *D. melanogaster* is the most advanced organism for which whole-animal studies of this kind have been performed. While most identified phosphosites were unchanged in terms of levels relative to a mock RNAi included in all experiments, a number of known and candidate kinase-targeted phosphosites, were altered in specific knockdown conditions. Examples of known substrates of shRNA-targeted kinases that exhibited a measurable change in phosphorylation in respective kinase-depleted embryos included Cdk1, Klp61F, and Hsp83 in 'wee' deficient embryos, and Histone H3, Med13 and Stat92E in *Cdk8* deficient embryos. In fact, we found that phosphorylation of one-third of respective *D. melanogaster* orthologs of literature-curated yeast *Cdk8* substrates (Sharifpoor *et al.*, 2011) that we identified were downregulated in *Cdk8* deficient *D. melanogaster* embryos. One phosphoproteome which exhibited a large number of candidate substrates based on pathway enrichment of downregulated phosphoproteins was that generated from embryos depleted of *gilgamesh*, the *D. melanogaster* casein kinase I gamma ortholog; the majority of phosphorylation we observed downregulated resided in proteins involved in Hedgehog (Hh) and Wnt/Wingless (Wg) pathways, consistent with a characterized role for Gilgamesh in mediating signaling of these pathways (Davidson *et al.*, 2005; Hummel *et al.*, 2002; Schertel *et al.*, 2013). Specifically, we observed downregulated phosphorylation of the G protein-coupled receptor Smoothed; Combgap, a direct repressor of Cubitus interruptus (Ci) and Wg target gene expression (Campbell and Tomlinson, 2000; Song *et al.*, 2000); Debra, a mediator of Ci polyubiquitination and degradation (Dai *et al.*, 2003); Retinoid- and fatty acid-binding glycoprotein, a lipophorin that binds and regulates Hh and Wg diffusion (Panakova *et al.*, 2005); Dyrk3, the human ortholog that directly phosphorylates Ci and induces its degradation (Varjosalo *et al.*, 2008); Interference Hedgehog (Ihog) interacting proteins Modulo and Karst (Guruharsha *et al.*, 2011); and other regulators of Hh signaling, namely Smg5, Belle, Adenomatous polyposis coli tumor suppressor homolog 2, Bx42, Chromator, Pitslre, and Rm62 (Nybakken *et al.*, 2005). This list of altered phosphoproteins undoubtedly includes both direct and indirect

Gilgamesh targets. Obviously, validation of *bona fide* direct Gilgamesh substrates would require additional information such as *in vitro* kinase activity towards the potential substrate, a protein–protein interaction, and functional assays. Based on the observations described above, we are confident that identified changes in the *D. melanogaster* phosphoproteome can be used to screen for authentic substrates and alterations in signaling downstream of the targeted kinase.

As expected the numbers of direct and indirect candidate kinase targets, which we considered as those phosphoproteins whose levels were downregulated relative to mock knockdown more than 1.5 fold, varied depending on the identity of the kinase depleted (Sopko *et al.*, 2014). This was expected since the number of phosphoproteins expected to have an interaction with an RNAi-depleted kinase will differ depending on the kinase, due to multiple factors including the function of the kinase, its expression level, localization, and connectivity (physical interactions with other proteins) (Ubersax and Ferrell, 2007). The number of downregulated phosphosites for the 19 kinase-deficient contexts we surveyed ranged from 752 to 22 and correlated with the degree of phenotype resulting from kinase depletion, indicating that extensive modulation of the phosphoproteome often translates to major morphological changes. For example, embryos depleted of the cyclin-dependent kinase *Cdk8* display extreme morphological defects and fail to hatch, consistent with the major effects on the phosphoproteome that we observed from knockdown of this general transcriptional regulator. On the other end of the spectrum, *Bub1*-deficient embryos look normal, consistent with the minimal effects on the phosphoproteome observed for near complete depletion of *Bub1*, hinting that this mitotic kinase functions redundantly with its paralog, *BubR1* (also known as Mad3). Redundant kinase targets could be uncovered from phosphoproteomic profiling of embryos deficient for two redundant kinases, for instance *Bub1* and *BubR1*, by co-expressing shRNAs targeting both, or one kinase-targeting shRNA in a background mutant for the other kinase. Such a scenario would reveal shared substrates, since the compensating kinase activity would be absent or hampered. Early *D. melanogaster* embryos serve up a superb experimental advantage in this respect since one can restrict RNAi specifically to the germline and hence negate any effects on viability, since an intact germline is dispensable for organismal development. In this way one can examine genetic scenarios where two mutations would be synthetic lethal and otherwise unattainable, for instance in yeast where the combination would result in arrested growth. Additionally, one can fine-tune the activity of the RNAi driver with the Gal4/UAS system in *D. melanogaster* (Brand and Perrimon, 1993) and therefore modulate the extent of knockdown, by altering temperature to look at graded effects (Staller *et al.*, 2013). Though single kinase knockdown alone may be sufficient to hint at redundancy, if kinase activity is hindered sufficiently to warrant detectable phosphosite alteration. In this case, individual phosphoprofiles for redundant kinases would exhibit a similar trend in change for compromised phosphorylation at shared sites.

Overlapping phosphorylation alteration patterns for any two kinases could additionally indicate participation of the two kinases in a common pathway, since one would expect shared changes in phosphorylation for targets downstream of

both kinases. One could decipher where they function by the extent to which they share similarity with phosphoprofiles generated from knockdown of known components of characterized signaling pathways. For example, to identify new components and targets of MAPK signaling, one could first define the individual phosphoprofiles associated with knockdown of Raf, MEK, and ERK, three kinases directly acting on one another in a signaling cascade. The phosphorylation of peptides representing true output of the pathway should trend in a similar direction for all three kinase knockdowns – either all up or all down – relative to knockdown controls, while phosphorylation events unique to each kinase will not. Phosphoprofiles generated from knockdown of genes in the same pathway would be qualitatively similar and share this pattern or partial pattern (Figure 2). This concept is similar to the approach that has been used extremely successfully in developmental genetics to identify components of signaling pathways, whereby genes with similar mutant phenotypes usually encode molecules that are part of the same biochemical pathways (Green *et al.*, 2011; Nusslein-Volhard and Wieschaus, 1980). This approach has been extremely powerful in particular using the *D. melanogaster* embryonic cuticle as a phenotypic readout. In relation to phosphoproteomic data, one could infer signaling hierarchy by substituting comparisons of cuticle phenotypes for similarity in patterns of thousands of phosphorylation measurements, generated from mass spectrometry analysis.

Additional information in terms of mapping network connectivity and shared enzymatic targeting could be gleaned from combining perturbations of protein kinases and phosphatases. For example, a shared protein kinase and phosphatase substrate should exhibit an exacerbated reduction in phosphorylation in a context where protein kinase perturbation, knockdown or mutation, is combined with overexpression of a counteractive phosphatase, as compared to kinase knockdown or phosphatase overexpression alone. In this scenario, the addition of phosphate onto the shared target would be hindered and the removal of phosphate enhanced. Conversely, overexpression of the culpable kinase and a reduction in opposing phosphatase activity could lead to elevated phosphorylation. Technically, an increase in phosphorylation may in fact be easier to detect by mass spectrometry than a decrease, though these types of combinatorial experiments have not yet been reported. These experiments should be relatively easy in *D. melanogaster* and budding yeast given the large number of available P-element insertion lines bearing UAS transgenes for Gal4-mediated overexpression and plasmid-based libraries for Gal4- and endogenous promoter-driven expression, respectively. Analogous genetic manipulations as those described above, to generate scenarios of target hyperactivity, have been demonstrated to result in altered cell growth and a means to successfully predict kinase substrates (Fiedler *et al.*, 2009; Sopko *et al.*, 2006). In these cases, growth was the phenotypic readout, however gene expression has also been used as a measure to predict kinase and phosphatase targets and redundancy between these enzymes (van Wageningen *et al.*, 2010). We expect that global protein phosphorylation measurements by mass spectrometry should serve as a better predictor of these relationships as compared to global gene expression, since these enzymes

Figure 2 Clustering of hypothetical phosphoproteomes generated from mass spectrometry of kinase-depleted cells by RNAi. Phosphosite level measurements generated from mass spectrometry of cells subjected to RNAi of MAP kinase (MAPK) signaling pathways components, relative to a control RNAi, are illustrated with a sliding color scale. Phosphorylation of the most downstream substrates of the pathway, directly targeted by ERK, exhibit downregulation in their levels for all three pathway kinase knockdowns while direct targets of individual upstream kinases in the signaling hierarchy are those downregulated phosphosites that lack overlap with knockdown of downstream kinases. Substrates of phosphatases activated by the depleted kinase can be deciphered as those upregulated phosphoproteins, using the same logic.

directly impact phosphorylation. In this way not only would global proteomic analyses map pathways, but could also be used to reveal critical nodes in signaling that may partially or completely overcome mutations resulting in pathway hyperactivity.

Because the number of protein phosphatases is under-represented in the genome relative to protein kinases, one might speculate their signatures would be less specific than protein kinases and their knockdown would affect larger proportions of the phosphoproteome. In fact, there appears to be no correlation between phosphatase ablation and impact on the phosphoproteome, relative to that of protein kinases – at least from the examination of yeast null mutants (Bodenmiller *et al.*, 2010). However, this observation could in fact be related to compensation for missing activity in deletion mutants over generations, as has been persuasively reported in

yeast (Teng *et al.*, 2013). Further support for the adaptation of null mutants is observations of different phenotypes depending on whether a kinase is targeted by a small molecule inhibitor or by complete deletion (Carroll *et al.*, 2001; Knight *et al.*, 2006). Consistent with this, Bodenmiller *et al.* (2010) observed a higher proportion of changes reflective of indirect effects with permanent deletion mutants as compared to short temporal inhibition of analog-sensitive kinases with small molecules. Conceivably, by comparing deletion mutants over generations or developmental time, one could identify compensatory rewiring events by identifying altered phosphorylation-dependent signaling by mass spectrometry. Further, by comparing complete gene knockout to incomplete depletion by RNAi-mediated knockdown with the same approach, one could identify off-target effects of RNAi reagents and compensatory effects resulting from gene knockdown, for example,

the stabilization of alternative isoforms (Figure 3). Such types of analyses have recently become more accessible given current advances to efficiently make deleterious mutations in *D. melanogaster* using CRISPR (Kondo, 2014).

In our recent study we demonstrated how kinase–substrate relationships may be illuminated from examining correlations in phosphosite changes measured by mass spectrometry (Sopko *et al.*, 2014). Specifically, we revealed how two phosphosites, correlating in their directionality of change among multiple

genetic contexts, multiple kinase-deficient conditions in our study, have a tendency to comprise a kinase–substrate pair. For instance, correlation of kinase autophosphorylation and phosphorylation of another protein can indicate activation of the phosphoprotein by the kinase, either directly or indirectly (Figure 4, top panel: positive correlation). On the other hand, inhibitory phosphorylation of a kinase will always be out of phase with phosphorylation of that kinase’s targets (Figure 4, bottom panel: negative correlation). We found enrichment for

Figure 3 A workflow for integrating systems genetics and proteomics to identify similar responses to genetic manipulation. A phosphoprofile is generated from phosphosites (PS) identified by multiplexed mass spectrometry methods analyzing genetically modified cells or organisms, manipulated by conditions (c) of RNAi, CRISPR-mediated knockout, overexpression, or combinations thereof. Clustering of phosphoprofiles generated from individual conditions are dictated by PS alterations, either down (cyan) or up (yellow) in levels relative to control. Neighboring phosphoprofiles post-clustering share similarity in their cellular response to the specific genetic manipulation(s).

Figure 4 Molecular scenarios explaining correlative and anti-correlative phosphorylation. Two phosphosites (PS) consistently responding in the same direction (positive correlation; +) or the opposite direction (negative correlation; -) in different genetic contexts can illuminate phosphosite functionality. Correlations, however, are not enough to distinguish between direct and indirect kinase targets.

genuine kinase-substrate pairs among 447 585 correlative pairs involving 2058 altered phosphosites (>1.5-fold relative to control RNAi) we identified from profiling 19 kinase-deficient genotypes. Significantly, the probability of identifying kinase-substrate pairs increased with the number of kinase-deficient conditions for which the directionality of change for the phosphosite pair correlated, positively or negatively. Application of this type of correlative analysis for the mining of existing large-scale phosphoproteomic data from different organisms and tissues has enormous implications in terms of mapping kinase-phosphatase networks and deciphering functional phosphorylation. Particularly, because uncovering functionality for a particular phosphosite does not rely on direct manipulation of the respective phosphoprotein, fewer experimental conditions than genetic manipulations are required to interpret the consequences of individual phosphorylation events. Moreover, having *a priori* knowledge of the function of a specific phosphosite – serving in an activating or inhibitory capacity – can facilitate interpretation of the other participating phosphosite of the correlative pair. We exemplified this in our study with a pair of phosphorylations that correlated positively in six kinase-depleted conditions: activating phosphorylation of the transcription factor STAT and a previously uncharacterized Sterile20-like kinase (Slik) phosphosite. Since this activating STAT phosphorylation is reduced in 'slik' deficient embryos, we predicted that Slik acts upstream of STAT and that phosphorylation of Slik kinase is required to promote STAT phosphorylation and DNA binding. We verified this prediction, by demonstrating that transcriptional targets of STAT are reduced in expression following *slik* knockdown. Our novel approach examining correlative phosphorylation to map kinase signaling uncovered a previously unrecognized role for Slik and pinpointed functionality of an individual Slik phosphosite. We anticipate that a similar strategy surveying the correlation of posttranslational modifications other than phosphorylation, derived *en masse* from mass spectrometry measurements, will shed light on the identity and mechanisms of relevant regulatory enzymes.

Given the large number of human kinase mutations associated with disease, understanding the global consequences of specific phosphorylation-impacted perturbations could prompt treatment tailored to aberrant signaling of specific pathways (Lahiry *et al.*, 2010). While current methods such as mass spectrometry can easily identify altered phosphorylation between samples, understanding the mechanisms by which these changes arise and deciphering impactful versus inconsequential changes on cellular and organismal phenotype remains a major challenge. We have recently reported how global phosphorylation surveyed under various genetic contexts can be used to generate a matrix of phosphoprofiles (Sopko *et al.*, 2014), permitting profile comparisons and correlative phosphosite analysis to predict kinase redundancy and map signaling networks. We expect that matrix expansion, incorporating additional genetic (for instance, combinatorial gene overexpression, or gene ablation or gene product depletion) and environmental contexts, will strengthen kinase-substrate and other types of network signaling mechanism predictions. This generic strategy is attractive given it can be applied to any organism or cell type. In conclusion, while the ability to catalog cellular measurements – DNA mutations, transcript levels, splice isoforms, protein levels and

modifications – is becoming cheaper, easier, and more comprehensive, efforts to understand the consequences of changes in cellular machinery are lacking and require the inception of new analysis methods, such as those described above.

Glossary

Arrayed library Arrangement of a collection ('library') of samples in specified positions on a microplate, slide, or chip.

Cellular phenotype Displayed characteristics or traits of a cell observable by microscopy.

Clustered regularly interspaced short palindromic repeats (CRISPR) genome editing A method based on a bacterial defense mechanism that allows targeted gene modifications.

Microarray Arrangement of large sample numbers on a small localized surface such as a chip or slide.

Over-sampling Sampling a higher number of images than required for 100% coverage in order to improve resolution and reduce noise.

RNA interference RNA-based technology to reduce gene expression levels in cells.

Texture feature Metric that defines pixel patterns in an image and statistically describes pixel distributions.

Introduction

An image says more than a thousand words. This is particularly true in the field of cell biology, which has always been based on the ability to visualize the cell and its components. In fact, cell biology became possible with the invention of the microscope, thus allowing for the first time to actually see a cell and define its contents. Over the decades and years that followed, revolutions in the ability to capture images enabled further, deeper insights into how cells work and function. The ability to resolve finer structures with instruments able to capture higher resolution images – through transmission electron microscopy in the 1950s and super-resolution microscopy nowadays – have led to astounding detail in understanding very small subcellular structures. The development of automated microscopy platforms in the late 1990s enabled the capture of thousands of images from biological specimens in a relatively short time frame, at moderate cost and with high resolution. High-content screening (HCS), i.e., the automated capture of high amount of cellular image data, was born.

History

HCS was made possible by the development of a microscope that is capable of acquiring a large number of images through an automated process (Taylor, 2010). Historically, HCS can be viewed as a direct consequence of earlier technical innovations: one was the development of the charged coupled device camera (CCD) that enabled the conversion of image data into numeric data values. Combined with improvements in cell-based assays using immunofluorescence techniques and the development of fluorescent protein-based reporter systems, it was possible to record a variety of cellular phenotypes with microscopy-based methods. The design of high-throughput genomic sequencers with automated instrumentation that were required for the human genome project in the early 1990s was paralleled by an interest to develop similar highly automated processes for the capture of large amounts of image data (Taylor, 2007). Lansing Taylor and

colleagues at Cellomics™ developed the first automated fluorescence microscope capable of acquiring a large number of images in an arrayed format, the Arrayscan™ in 1996. Quickly after the launch of the Arrayscan™, several other HCS platforms were developed and adopted by both pharmaceutical and academic research institutes. Another breakthrough that brought HCS to a larger research community was the availability of RNA interference libraries in the early 2000s that enabled the use of such libraries in loss-of-function screens. Following the identification of most coding gene products in the human genome and the genome of other model organisms, large-scale arrayed genomic libraries became available that enabled the analysis of cellular gene function on a genomic scale (Figure 1) (Boutros *et al.*, 2004; Silva *et al.*, 2004; Moffat *et al.*, 2006). These developments further consolidated the use of HCS in many research labs as a primary method of choice for both basic scientific research and drug discovery. Most major universities and research institutions now house at least one HCS platform. The most striking advantage of HCS over common fluorescence microscopy techniques is the possibility to analyze a large number of samples in a relatively short time frame. In fact, recent developments in the imaging hardware has led to instruments capable of acquiring high-resolution images that rivals the image quality of conventional confocal microscopes.

'Content' is typically in the form of an image or video that will be converted into binary data values by a process termed image analysis. Sometimes the terms HCS and high-throughput screening are used interchangeably. This is not necessarily correct as high-throughput screening refers to screening a large set of samples with single data values as output, whereas HCS refers to extracting a large number of features from a large set of images. Today, HCS is used in translational drug discovery as well as fundamental academic research. Applications range from the identification of chemical hit compounds in primary drug screening campaigns and profiling of cellular responses to perturbations to studying fundamental questions of cell mitosis, morphology, and heterogeneity. HCS has become quite complex and can make use of diverse techniques such as live cell imaging, whole animal imaging, spheroid cultures, and others that will be discussed below.

Figure 1 Milestones in HCS. Main developments in the hardware required for HCS leading to the development of the Arrayscan™ are shown in blue color. Improvements in cellular assay technologies with the two main reporter types – Immunofluorescence and fluorescent reporter proteins – are shown in yellow. Milestones in functional genomics that led to improved arrayed libraries are shown in green.

Experimental Setup

There are six basic components for HCS experiments:

1. cells,
2. perturbations,
3. assays,
4. instrumentation,
5. image analysis, and
6. statistics.

A schematic workflow diagram for HCS is shown in **Figure 2** that will be explained in more detail below. Briefly, a cell-based system that is best suited to display the phenotype of choice will be subjected to a chemical, biological, or genetic perturbation. The resulting phenotypic changes that are visualized by specific assays will then be recorded on a HCS imaging plate reader. The images will be converted into image data through image analysis and statistically evaluated.

Cells

The cell-based model used in HCS can be relatively simple (e.g., a single layer of a standard cancer cell line such as HeLa cells) or quite complex (e.g., whole zebrafish embryos). Depending on the choice of model system, there are a number of challenges that need to be overcome. Some examples of cell-based model systems that are typically used in HCS are shown in **Table 1**. The choice of cell system is largely determined by the desired output. For instance, when the main aim is to identify hit compounds from a large collection of chemical compounds, a 2D layer of cancer cells with an unlimited supply of cells can be a good choice. Similarly, in whole genome siRNA knockdown experiments, the use of generic cell lines such as HeLa or Schneider S2 have shown great utility (Kiger *et al.*, 2003; Boutros *et al.*, 2004; Eggert *et al.*, 2004). Some cell biology questions require the use of specialized cell types or primary cells that may better reflect the physiological phenotype. However, when supply of primary cells is limited, there may be restrictions in the ability to perform high-throughput screening and smaller libraries are used. Another consideration is that primary cells from different donors are quite variable and can introduce complications for phenotypic analysis. One possibility is pooling of samples from multiple donors to overcome this problem, although for

Figure 2 Schematic overview of steps in HCS experiments. A typical HCS experiment proceeds in five steps. Cells are subjected to a perturbation using siRNA, cDNA, CRISPR, peptide, or chemical libraries. A suitable assay for monitoring a cellular phenotype will be used such as immunostaining of a protein with a fluorescently tagged antibody as depicted here. Images of the cells will be acquired in a dedicated high-content imaging platform such as the PerkinElmer OperaLX. In the end, the images will be processed and subjected to image analysis in order to extract data values. These data values require stringent statistical evaluation.

some cell types such as immune reactive cells this is not possible.

There are two ways to feed cells into the HCS experiment. One is to deposit cells into standardized microplates (96-,

Table 1 Examples of cell models commonly used in high-content screening applications

<i>Cell model</i>	<i>Culture type</i>	<i>Applications</i>	<i>Scale</i>	<i>Culture time</i>	<i>Comments</i>
HeLa cells	Monolayer	cDNA, siRNA, and drug	HTS	Hours–days	Other commonly used adherent transformed cell lines are A549, HepG2, HEK293 cells. Large quantities of cells are available, thus enabling higher throughput applications
Fibroblasts	Monolayer	cDNA, siRNA, and drug	MTS	Hours–days	Fibroblasts are available from genetic mouse models, thus offering the use of a genetically modified system for HCS. Cell numbers can be limiting
Schneider S2	Monolayer	siRNA	HTS	Days	Drosophila cell lines such as Schneider S2 have proven highly useful for investigation of cellular processes and have pioneered some of the early siRNA screening work
Primary neurons	Monolayer	siRNA and drug	MTS	Days–weeks	Primary neurons from rat or murine sources can be limiting in number. Culture conditions require a higher level of experience and image analysis of neurons can be quite challenging
iPS-derived cells	Monolayer or 3D	siRNA and drug	MTS	Weeks–months	Induced pluripotent cells from patients' fibroblasts offer a unique opportunity to study genetic diseases in a human cell type. Differentiation of these cells can take weeks and is a challenge for experimental setup.
Tissues, embryos, worms	3D	Morpholino, siRNA, and drugs	LTS	Days–weeks	Zebrafish and Drosophila embryos have been used in HCS, as well as <i>Caenorhabditis elegans</i> worms. Imaging depth and image analysis remains a challenge for the investigator
Tumor spheroids	3D	Drugs	LTS	Weeks	Multiple systems for generating 3D models of cells are available from commercial vendors. An increased use of 3D models systems in HCS can be expected in the future

Abbreviations: HTS – high-throughput screening; LTS – low-throughput screening; MTS – medium throughput screening.

384-, or 1536-well format) that are acceptable for most HCS platforms. The microplates can be pretreated with agents that help cells attach or differentiate. Subsequently, the cells are subjected to a perturbation experiment as outlined below. This approach is less stressful for the cells, as they are given time to recover from cell seeding and is usually done when pretreatments are necessary such as addition of growth factors or differentiation factors. An alternative method is to deposit cells on top of a perturbation reagent, for instance onto spotted siRNA oligonucleotides (Erfle *et al.*, 2007) or surface-coupled chemical entities (Miyazaki *et al.*, 2010). This approach has the advantage that it allows miniaturization and ultra-high-throughput screening through the production of dense microarrays on slides.

The whole field of HCS in drug discovery is currently undergoing a paradigm shift, recognizing that adherent 2D cultures may not be accurately reflecting the physiological tissue context. Either tissue or whole animal imaging, or – in a drug screening pipeline – the use of 3D model systems will become an important step forward toward realizing HCS in cell biology under more physiological conditions. For instance, a high-content imaging platform specifically designed for quantitative evaluation of 3D tumor models has recently been developed (Celli *et al.*, 2014). Another exciting development in this regard is the design of the Vertebrate Automated Screening Technology (VAST) BioImager™ platform for whole zebrafish organ-level imaging (Pardo-Martin *et al.*, 2010).

Another area of intense research is the use of induced pluripotent stem (iPS) cells in high-throughput screening (Desbordes and Studer, 2013; Sherman *et al.*, 2011; Földes *et al.*, 2014). iPS cells derived from human fibroblasts can be differentiated into a wide range of cell types, thus enabling for the first time HCS experiments in primary human cells that are otherwise not accessible such as neurons or cardiomyocytes. One of the biggest challenges is that due to the long differentiation protocols the cells may need to be cultured for several days, if not weeks, in the same microplates before images can be acquired. Such modalities require further optimization of the cell sample preparation and culture in order to be applicable to large-scale HCS measurements.

Perturbations

Next, the cell-based system is subjected to a perturbation such as small molecule treatment or siRNA-mediated gene knock-down. The aim of such perturbations is to identify hit compounds within a large collection of chemical entities or to identify genes involved in cellular pathways. Perturbations can be any type of arrayed or pooled library including small molecule compounds, siRNA, cDNA, peptides, antibodies, or clustered regularly interspaced short palindromic repeats (CRISPR)-based genome-editing tools (Heintze *et al.*, 2013).

There are some instances where high-content imaging has been used to profile populations of cells without any perturbation treatment, for instance when assessing cellular (Snijder *et al.*, 2012) or organelle heterogeneity (Ferraro *et al.*, 2014). The main challenge for perturbation experiments is delivery of the reagent. Some reagents such as siRNA, cDNA, and genome-editing tools have to be delivered into the cytoplasm or nucleus of the cell. This is most commonly achieved by transfection using lipofection-, chemical-, or electroporation-based methods. In some cases, there is no need to deliver the component into the cell, for instance when antibodies or compounds are profiled for binding to cell surface receptors. Small molecule compounds generally don't require transfection, although electroporation may help in the delivery of small molecules that are not cell permeable.

There are two methods for reagent addition as outlined above: in reverse transfection methods, the reagent can be dispensed into empty plates or spotted onto slides (Erffle *et al.*, 2007). Forward genetic methods use cells cultured in plates and the reagent will be added to the medium. The use of cell arrays has the advantage that a higher number of samples can be studied in a shorter time and at lower cost. After a specified time, the plate will be fixed for end-point assays or subjected to (time-lapse) live cell imaging in HCS platforms.

Assays

In general, any HCS assay falls into one of three main categories:

- visualization of a protein, protein complex, or protein modification,
- visualization of a cellular structure, such as an organelle, and
- visualization of a cellular process (e.g., cell death, protein trafficking, or protease cleavage).

Any of these structures and processes requires visualization and conversion of image data into binary data. As such, the cellular information (e.g., identity of an organelle) requires detection as a fluorescent signal using either attachment to a fluorescent protein or binding of a fluorescent reagent. Once a structure is labeled with a fluorescent tag, the following major phenotypes can be detected:

- a. number of cells, subcellular objects,
- b. subcellular changes in localization,
- c. co-localization of multiple markers,
- d. phenotypes measured by intensity features: mean fluorescence intensity of objects,
- e. phenotypes measured by morphology features: size (area and volume) and shape of objects, and
- f. phenotypes measured by texture features.

Typically, multiple features are measured. Using positive and negative controls that produce the desired phenotype of interest, it is possible to evaluate the feature that gives the best signal to noise ratio and dynamic range. The large amount of data collected by extracting multiple features poses opportunities and challenges in data analysis. Improvements in the

analysis using multivariate profiling of hundreds of features have been made to exploit this strength and address the problem (Loo *et al.*, 2007).

How can these objects and processes be visualized? Generally, one can distinguish between visualization of an endogenous process and the introduction of a reporter construct to extract information of an endogenous process. Direct visualization of an endogenous process has been greatly facilitated by the development of immunofluorescence techniques using antibodies that bind to specific cellular proteins. Such immunostaining can be used to quantify the amount of a protein within a cell or protein–protein binding (e.g., by using two different color-tagged antibodies, split fluorescence proteins or Foerster resonance energy transfer (FRET)-based methods). When analyzing organelles, one could use immunostaining for a marker protein localized to the specific structure. In addition, multiple companies now offer small molecule-based dyes that selectively stain specific organelles for fluorescence microscopy. Most of these techniques require fixed samples and end-point assays. An alternative to immunostaining methods is the use of fluorescent proteins for tagging proteins or monitoring protein and metabolic activities. Following the cloning of green fluorescent protein (GFP) from *Aequorea victoria* in 1994 (Chalfie *et al.*, 1994), there are now a wide range of different colored variants available that cover the entire visible spectrum. Translational fusions of FPs with a protein of interest allow monitoring of protein amount, trafficking/movement, and protein–protein interactions. Furthermore, FP-based sensor proteins have been generated that allow investigations of calcium levels, intracellular pH, mitochondrial redox potential, cyclic AMP levels, protease activity, phosphorylation, and protein–protein interaction using FRET (Tsien, 2009). Similar to proteins, other cellular components can be readily visualized. For instance, DNA or RNA-intercalating agents allow the quantification and identification of DNA/RNA in cells. Similarly, membranes in the cell are usually identifiable by lipophilic fluorescent probes that insert in the membrane of choice, sometimes selectively based on the lipid composition of the membrane type.

From a cell biology perspective, the analysis of organelle biogenesis, trafficking, and function are key elements that have been addressed using HCS. Any of the major organelle types have been analyzed by HCS, including the nucleus in mitosis (Neumann *et al.*, 2010), the Golgi apparatus (Galea and Simpson, 2013), the *trans*-Golgi network (Ferraro *et al.*, 2014; Wendler *et al.*, 2010), endosomes (Collinet *et al.*, 2010), secretory granules (Ferraro *et al.*, 2014), mitochondria (Ivatt *et al.*, 2014), autophagosomes (McKnight *et al.*, 2012; Kriston-Vizi *et al.*, 2010), centrosomes (Dobbelaere *et al.*, 2008), the actin cytoskeleton (Liu *et al.*, 2009), and viruses (Mercer *et al.*, 2012). The main features of interest are the number of organelles (counting individual objects), the intensity of objects (intensity of individual objects), and measuring the size of organelles (measuring length or area). One consideration is that small objects will require a higher resolution platform compared to analysis of larger structures. Another consideration is cell and organelle variability, that has been addressed using population-based measurements (Snijder *et al.*, 2012) or using micro-patterning in microplates (Schauer *et al.*, 2014). Whole cell measurements are usually required when cell

Figure 3 Example images from high-content screens at the Translational Research Resource Centre, London. The top row shows different organelles that have been visualized with fluorescent protein tags (autophagosomes, AV, upper left corner), chemical staining (Mitotracker, mitochondria, upper middle panel), or antibody staining (Weibel–Palade bodies, WPB, upper right corner). Nuclei can be counted to give insight into processes that regulate multinucleation (middle left panel) or number of virus-infected cells (green cells in center panel). HCS can also be used to visualize more complex processes such as monitoring induced iPS cell differentiation into neuronal cells (middle right panel), membrane polarity (lower left panel), or protein localization (in this case the adapter protein Grb2, lower middle panel). When using a confocal microscope and several z stack images are acquired, cellular organelles can be visualized in a 3D context such as shown for autophagosomes in a MCF-10 A human mammary spheroid section in the lower right panel.

morphologies, neuronal phenotypes, total protein levels, or general cell numbers are recorded.

Some example images of HCS experiments are shown in [Figure 3](#). Please note that – depending on the instrument and the choice of fluorescent marker – multiple fluorescent reporters can be visualized in the same experiment.

Instrumentation

The key hardware component is a HCS imaging plate reader. Since the Arrayscan was launched in 1997, multiple other companies have designed alternative HCS imaging platforms and continue to improve on design and functionalities of these instruments. Today, there are about a dozen different types of instruments on the market, with varying hardware components and functionalities ([Table 2](#)). In general, the choice of a HCS system is a decision about speed/throughput

versus image quality. Higher resolution and higher quality images generally take longer time to acquire, although certain features such as parallel image acquisition by multiple cameras can reduce acquisition times significantly.

The main features of HCS imaging systems are:

- light source,
- autofocus,
- cameras,
- optical sectioning, and
- image analysis software.

The basis for all HCS platforms is a powerful light source that can be either laser-based or light-emitting diodes (LEDs). Most systems use between three and five laser-based light sources, while others such as the Arrayscan™ is based on a solid-state LED light engine. The autofocus mechanism can be laser-based or software controlled or a combination of both.

Table 2 Selected examples of high-content imaging platforms

Platform	Light source	Autofocus	Camera	Optics	Reference
Arrayscan TM XTI (Thermo scientific)	LED solid-state light engine	Software-controlled	H1 camera with large format charged coupled device (CCD) (2208 × 2208)	Zeiss AxioObserver	www.thermoscientific.com
InCell Analyzer 6000 (GE Healthcare Life Sciences)	Up to four solid-state lasers	Software controlled or laser-based	Large format sCMOS camera	Epifluorescence based line scanning confocal system	www.gelifesciences.com
ImageXpress [®] Ultra (Molecular Devices)	Up to four solid-state lasers	Laser-based	Large sensor CMOS detector	Laser scanning confocal with software configurable detection pinhole	www.moleculardevices.com
Opera Phenix TM (PerkinElmer)	Up to five solid-state lasers	Laser-based	Up to four large format sCMOS cameras with simultaneous acquisition	Spinning microlens disk, Synchrony TM optics	www.perkinelmer.co.uk
BD Pathway TM 855	Metal halide lamp	Laser-based	CCD camera	Confocal spinning disk	www.bdbiosciences.com
Acumen [®] Cellista (TTP Labtech)	Triple laser excitation		photo-multiplier tubes detector array	Widefield F-theta lens for whole well imaging	ttplabtech.com
Cytation TM 3 (Biotek)	High-power LED	Software-controlled	CCD		www.biotek.com
HC High Content Analysis System (Nikon)	Lasers	Piezo-based	CCD, CMOS	Nikon Eclipse Ti	www.nikoninstruments.com
Scan $\wedge$ R (Olympus)	150 W Xenon or Mercury-Xenon	Software-controlled or laser-based	CCD Hamamatsu	Olympus IX81 and IX83 microscope	www.olympus.co.uk
Cell Voyager CV7000 (Yokogawa)	Solid-state lasers	Software-controlled or laser-based	Up to three large format sCMOS cameras	Microlens-enhanced dual Nipkow disk scanning	www.yokogawa.com

Note: Information taken from vendors websites. Some vendors offer multiple HCS platforms and for simplicity, a selection is shown.

Laser-based mechanisms focus on the surface of the plate type used and is generally quick. Software controlled acquisition of iterative z height sampling can be more time-consuming and focuses on a cellular staining. Initial problems with software-based auto-focussing were delays in focussing when empty wells or wells with detached cells were found, but newer software algorithms circumvent this problem. The choice of camera will largely determine the resolution of the image. Generally, a large format complementary metal-oxide semiconductor (cMOS) or CCD camera is used. An alternative to the use of cameras is instruments based on scanning laser-imaging cytometry that utilize photo-multiplier tubes (PMTs) for detection of the signal. These platforms provide an advantage in terms of speed and do not require image stitching as most camera-based systems do. However, these instruments typically don't have the same level of image resolution. When acquiring images, over-sampling is sometimes done in order to gain a better image quality.

Most HCS instruments are modular with the opportunity to include add-on options such as robotic integration, bright field illumination, injectors or environmental control.

Nowadays, HCS instruments have reached an optical capability that rivals standalone fluorescence microscopes.

High-Content Analysis

Once images are acquired, one of the major challenges is to extract quantitative data by high-content analysis (HCA). One should note that the human eye has evolved to pick up minor differences in patterns and is probably the most reliable tool to identify phenotypes. Since this is no longer possible once a large number of samples are to be inspected and sometimes overlaying phenotypes can mislead the eye. The main challenge is to instruct computer software to extract quantitative data from raw images based on the strength of a given phenotype. Quantifying cellular (Futamura *et al.*, 2012) or subcellular features, HCA consists of two major components: (1) image analysis where the phenotypic features of interest are extracted and subjected to and (2) statistical analysis. Both fields are evolving dynamically: mathematical methods in low-throughput cellular image processing such as active contours

are applied in HCA (Yu *et al.*, 2010), and HCA-specific statistical tools have been developed (Malo *et al.*, 2006, 2010).

Image analysis

A multitude of software options are available for image analysis and feature extraction. For example, commercially available HCA programs such as InCell Analyzer (GE Healthcare), Acapella (PerkinElmer Inc.) with Spotfire (TIBCO Software Inc.), or Metamorph (Molecular Devices, LLC.) bundled with specific HCS platforms, standalone proprietary software as Matlab (Mathworks Inc.) with Image Processing Toolbox as well as open-source software such as CellProfiler (Carpenter *et al.*, 2006), ImageJ (Abramoff *et al.*, 2004), or one of its variants, Fiji (Schindelin *et al.*, 2012). The statistical data analysis functions are either built in a HCA software or developed as a standalone software such as CellProfiler Analyst or R-project (R Core Development Team, 2014) the language, created and extended by mathematicians.

1. Commercial HCA software has the simplest user interface and standardized methods. Their closed source code results in lower flexibility.
2. Free standalone software specialized for image analysis and statistics offers higher flexibility, for the price of a steeper learning curve. ImageJ and R have a large user community and a wide range of application: ImageJ covers image processing applications from astronomy to biology (Schneider *et al.*, 2012), and the R statistical computing language is used from general statistics to specific computational biology and bioinformatics through the Bioconductor project (Gentleman *et al.*, 2004), that includes cell-based HCA packages like cellHTS2 (Boutros *et al.*, 2006) and HTSanalyzeR (Wang *et al.*, 2011).

Commercial HCA software bundled with HCS systems are designed for easy use for the biologist. These products are optimal in a standardized pharmaceutical corporation environment, where millions of samples are screened. In that case the assay can be designed based on the requirements of the HCA algorithm, for example, staining cytoplasm if the software detects the cell by a cytoplasmic marker. This software often uses their proprietary image file format, which limits the input source to the specific plate reader. The comparison between different bundled proprietary HCA software solutions is difficult, since the underlying image processing algorithm is hidden. Customization of the analysis can be a challenge because of the proprietary environment and a newly developed script can only be used by the HCS user group of the given vendor.

On the other hand, free HCA software facilitates algorithm customization and enhances the publication of new scripts, plugins, and macros. For instance, ImageJ has more than 300 macros, over 500 plugins available on the ImageJ website, and the number of R packages is more than 6000. There is a fair chance that customized solutions for a nonstandard problem can be found in the ever-increasing knowledgebase of ImageJ and R mailing lists at Stack Overflow and Nabble. Open-Source HCA allows easy connections with related fields such as computational chemistry (Lepp *et al.*, 2009) with integration tools such as KNIME.

A HCA workflow is typically being set up and tested on some sample images. The aim is to create a pipeline with optimal parameters that can analyze a wide range of images of the whole assay. The whole image stack contains negative controls as well as hits that express potentially stronger phenotype than positive controls, therefore a fully automated HCA image analysis workflow must be robust. In order to facilitate optimization, the number of image processing parameters should be kept at a minimum and must be intuitive for someone, who is not an expert in image analysis.

HCA workflow

A typical HCA image processing workflow consists of noise reduction, segmentation, and feature extraction steps (Figure 4).

Noise reduction

The noise reduction serves to improve the signal on an image by reducing the inherent imperfections of the imaging system such as stuck pixels in the camera, or unspecific staining. Computationally cheap implementations are optimal in a HCA environment, like the multi-threaded median filter, or the rolling ball algorithm in ImageJ.

Segmentation

Segmentation is a binary classification that labels each pixel as either foreground or background. The segmentation can be (1) global, when a single threshold is applied to all pixels in an image or (2) local or adaptive, when separate thresholds are used in a part of an image. The parameter number of a segmentation algorithm must be kept at a minimum in order to ensure the usability of a HCA workflow. Otsu and Isodata are particularly fast HCA segmentation algorithms that calculate their single parameter directly from the image pixel information. Nonlinear multi-parametric supervised machine learning-based methods can further improve the accuracy of the segmentation step for the price of more labor-intensive training process, and its HCA use is even more promising at cell classification level (Horvath *et al.*, 2011).

Segmented pixels are grouped into objects. Higher than single pixel level, objects consist of foreground pixels based on neighbor connectivity. ImageJ uses 8 pixel connectivity in 2D images where neighboring pixels form an object by connecting horizontally, vertically, or diagonally, touching each other's edges or corners. In the future 3D HCA is expected to use voxels instead of pixels and 26-neighborhood connectivity.

Feature extraction

Objects are labeled and quantified in the feature extraction step. Data is getting more complex and compressed at each processing step. The acquired information encoded into several gigabytes of 12 bit depth gray level pixels is first converted to 2-bit depth binary segmentation, then a table of measurements, where each line represents measurements of a cellular or subcellular object. Features are classified as intensity-based, morphology and texture-based features. Intensity-based features describe the object by the statistics of its pixel intensities: mean, median, mode, minimum, maximum, standard deviation, and total pixel intensity. Morphology-based features are shape descriptors: area, perimeter, Feret's diameter (maximum

Figure 4 Image processing workflow of a multichannel image of A549 cells imaged by ImageXpress Ultra, with 20x lens, nuclei stained with Hoechst 33342, autophagosomes stained with monodansylcadaverine. The original nuclear channel of a sample cell was smoothed with a median filter, then segmented with *k*-means clustering algorithm, the nuclear object was selected and quantified: (a) from left to right. The original autophagosomal channel of the (a) sample cell is shown, where the bleed through from nuclear channel was removed by using the nuclear mask, the autophagosomes in the remained area of the cell was segmented by IsoData algorithm and the features were extracted: (b) from left to right. A sample image of the autophagosomal channel (c), segmented by region growing with commercial HCA software (d), and with the (a–b) workflow (e). The overlay image shows the difference between (d–e) segmentations (f). All scale bars are 20 μ m. StdDev, standard deviation.

calliper), circularity, and aspect ratio. Texture features (reviewed at [Huang and Murphy, 2004](#)) statistically describe pixel distributions and can be quite numerous: the major part of the 2600 image features that the WND-CHARM image classifier ([Orlov et al., 2008](#)) computes are texture features. However, most of those texture features are redundant, which requires an additional feature selection step. The computationally expensive algorithms make those software solutions less feasible in current HCA pipelines but can become possible in the future.

Statistical analysis

Although being a lengthy text file, the feature table can be a 1000-fold smaller representation of the initial high-content image dataset. Focused on statistics and developed by mathematicians and statisticians, the free R software has the scalability and flexibility to analyze large HCS data tables. A typical statistical HCA workflow in R starts with further data compression and finishes with an ordered list of the samples that specifies a hit list. The multidimensional feature space of many objects in several images per well should be averaged to one single value per well with a simple R script, and format as an input data for the cellHTS2 package ([Boutros et al., 2006](#)), the R Bioconductor project's HTS module.

The aim of a cellHTS2 workflow is to put the samples into order based on the strength of the phenotype of interest and after choosing thresholds enable the researcher to generate a hit list.

The main vignette of cellHTS2 (complete version, available online) describes a full data analysis workflow with sample R code, here we overview the process. Scoring and optionally, annotation follow data normalization. Per plate median, control- and non-control based algorithms such as B-score ([Malo et al., 2006](#)) were implemented for normalization and standard scoring methods like Z-score are available as well. As a result, a report document is generated in web browser-readable HyperText Markup Language (HTML) format, where screen quality control measurements are computed along with an ordered sample list based on the scores.

Data storage

Through HCS, a large amount of data is collected that poses challenges in terms of data handling and data storage. Generally, multicore CPUs and several terabytes (often petabyte) for data storage are needed. Multiple databases exist where HCS data and images can be deposited and mined by the research community, including OMERO ([Swedlow et al., 2003](#)), GenomeRNAi ([Schmidt et al., 2013](#)), RNAiDB ([Gunsalus et al., 2004](#)), FLIGHT ([Sims et al., 2006](#)), and the JCB DataViewer ([Hill, 2008](#)).

3D imaging presents novel opportunities and challenges for image analysis and data storage. While feature extraction of phenotypes in classical HCS has been done on a parameter per image or parameter per cell basis, there are now more modalities that can be interrogated, taking into account the 3D distribution of features. For example, 3D volumetric information can be analyzed in fruit fly embryos ([Kriston-Vizi et al., 2011](#)) and parameters can be defined as feature per 3D structure or feature relative to location within a 3D structure per cell per field. As such, there are multiple levels of complexity, opening up the possibility to collect thousands

features ([Tang et al., 2011](#)). This notion underscores a current shift in a switch from HCS to 'high complexity screening' (HCxS).

High-Content or Low-Content?

An analysis in 2014 revealed that a large number of published high-content screens only present data from one or two features ([Singh et al., 2014](#)), suggesting that most HCS is in fact low-content. One possible explanation is the lack of appropriate tools for data analysis. For instance, commercial bundled software usually restricts users to analysis of few predefined parameters and are used mostly by novice users that prefer simple methods over high-content. As such, there may be a gap between novice users and HCS experts who have better knowledge of the available bioinformatics and data analysis tools. Significant progress has been made to enable multi-parametric analysis with free available software tools that should help bridge this gap in the future. For example, machine learning and multi-parametric classification tools such as CellProfiler Analyst ([Jones et al., 2009](#)), CellClassifier ([Ramo et al., 2009](#)), Enhanced CellClassifier ([Misselwitz et al., 2010](#)), or Advanced CellClassifier ([Horvath et al., 2011](#)) enable the selection of cells that display a certain phenotype of interest and facilitate automated feature extraction in large image data sets. In addition, multidimensional profiling can help to cluster multiple feature distributions in order to classify hits based on multi-parametric readouts ([Singh et al., 2014](#)). Further developments in this area will enable the realization of truly HCS applications even for newcomers to this exciting technology.

Conclusion

It can be expected that HCS will continue to contribute substantially to our understanding of cell biology in the future. The capability to miniaturize experimental setup, time and cost through this technique will enable discoveries of cell biology to be made on a much larger scale. One of the bottlenecks is that more advanced imaging techniques such as super-resolution microscopy are not applicable to automated image acquisition yet, partly due to limitations in the hardware and time constraints that make it unreasonable. Current developments in this area include the integration of microfluidics, allowing a high degree of miniaturization and a higher level of spatiotemporal and environmental control over live cell imaging ([Cheong et al., 2009](#); [Upadhyaya and Selvaganapathy, 2010](#)). Flow cytometers such as the ImageStream™ are available now that combine flow cytometry with high-content imaging at reasonably high resolution, thus allowing rapid single-cell HCS. Recently, a high-throughput imaging microscope for high-speed imaging of entire live embryos based on light-sheet microscopy has been developed ([Tomer et al., 2012](#)) that is a milestone step toward realizing even more complex HCS. Furthermore, a HCS system based on fluorescence lifetime imaging (FLIM) for improved measurement of FRET has been described for improved HCS of spatiotemporal dynamics *in vivo* ([Kumar et al., 2011](#)).

Overall, HCS has enabled the analysis of cells and organelles in a much more time- and cost-effective manner when compared

to individual probing of single gene perturbations. Current instrumentation has reached a quality that rivals conventional standalone instruments and will continue to make essential contributions to our understanding of general cell biology.

Introduction

The exciting technological advances allowing high-throughput biological research have promised to unlock the secrets of our genome. However, the initial excitement over new technologies as usual quickly turned into challenges of how to efficiently integrate, analyse, interpret the data produced, and enable knowledge discovery (Bellazzi, 2014). Since a holistic approach is the only way to understand systems-level phenomena, we need to integrate many heterogeneous sources at multiple layers of detail and different levels of completeness (Lauffenburger, 2012). For example, to fully understand the cellular function of a protein complex, information must be collected and combined for the expression, posttranslational modification, interactions, and localization of all its subunits. The approaches toward addressing such challenges have shaped a whole new scientific discipline called 'Integrative Systems Biology.'

Many databases, resources, and tools have been built to address the big challenge of providing the biological research community with easy ways to extract information from high-dimensional biological data. The various resources report information on multiple organisms and layers of the cellular regulation (e.g., genomics, proteomics, interactomics, etc.) derived from a variety of experimental methods (Berger *et al.*, 2013; Joyce and Palsson, 2006; Lee *et al.*, 2012; Rodríguez-Ulloa and Rodríguez, 2008).

However, the complexity of the biological data as well as the way these data are stored and processed in the different resources, pose significant obstacles in the current integration efforts. In this article we review the data integration challenges and solutions, and illustrate them with an example protein complex (Figure 1).

Challenges

Inconsistent Nomenclature

Consistent nomenclature between biological entities like genes and proteins is of major importance for any type of data integration. So far, different public databases use several different competing standards for assigning names to the different types of biological entities, which causes ambiguities in biological nomenclature (Fundel and Zimmer, 2006). This results in two problems: the same gene or protein will often be provided by different resources under different names or identifiers (e.g., the tumor necrosis factor (TNF) is also known as TNF-alpha, TNF-a, cachectin, TNFA_HUMAN, P01375, etc.) and the same gene or protein names are assigned to homologs from different organisms. Although most databases list synonyms or cross references to other databases, these lists are rarely complete. Another technical complication is the use of Greek letters or special characters in entity names (e.g., TNF α),

which is no problem for human readers, but can pose problems for a computer, in particular when extracting information from the biomedical literature. In our example, the same subunit of the complex may be referred to by different identifiers in different interaction databases.

Lack of Standardization

The lack of standardized formats for the representation of the data provided, in particular by new technologies, poses a significant practical obstacle to data integration. The technology and software used for producing and analyzing each individual type of data is often tightly linked to the form in which the data are presented. Because technologies and analysis tools change all the time, data standardization efforts are continuously trying to catch up. Therefore, data from new technologies have often not been deposited in standardized repositories and instead must be extracted from the primary articles, sometimes from the images and graphs within (El-Khatib *et al.*, 2000). Even when data have been aggregated in databases, each database tends to adopt its own standard and annotation practice. For example, the protein interaction databases IntAct and BioGRID report 89 and 16 interaction partners of NFKB2, respectively, based on the same study (Bouwmeester *et al.*, 2004).

Incomplete information on the data provided by the different resources, is another very common phenomenon, with a significant impact on the data integration efficiency and reliability. The same phenomenon is often observed at the supplementary information following published articles. Since there is no general agreement on the data depth that should be provided by each database, it is upon the publication authors or the data resource developers to select the data they provide. Missing information very often concerns details on the experimental assays or references to the source literature. For the protein complex example, important information could be missing such as the experimental assay used or even the source publication. This was a problem in the past but has been addressed by the Proteomics Standards Initiative – Molecular Interactions (PSI-MI) workgroup (Kaiser, 2002).

Limitations of Manual Curation

Even if manually curated data have been for years assumed to be of high-confidence, manual-curation approaches suffer from considerable limitations. Clearly, sometimes the reason is human errors introduced when manually extracting information from the literature or too uncritical trust in the claims made in the peer-reviewed literature. However, maybe the biggest challenge is simply to keep up with the ever-growing literature (Turinsky *et al.*, 2010). It is not feasible for curators to go through every published articles and manually annotate every type of evidence reported, and many databases thus focus on specific diseases, species, or experimental methods

Figure 1 Illustration of a common data integration workflow. (a) To illustrate the typical steps in data integration, we use a protein complex as an example. (b) To start, data from multiple sources are collected. Data can be derived from databases, manual literature curation, supplementary information, or article figures. (c) To combine the diverse information, the nomenclature and representation of the data by the various resources is standardized. For that reason, naming standards, controlled vocabularies, and ontologies are often used. The results concerning the protein complex from the different resources can vary (the colors of the edges are respective to the resources); specific complex subunits may be missing or additional subunits may be present, depending on biological and technological reasons. (d) To complement the existing data, text-mining and prediction methods can provide additional information on the complex subunits, which was not captured by the existing literature. (e) The agreement of each dataset with a common reference set (gold standard) is quantified and a confidence-scoring scheme is developed enabling direct comparison of the quality of each dataset. (f) The final complex contains interactions derived from experimental and predicted information (gray edges), while the thickness of the edges is respective to the quality of the information supporting each link, as resulted from the quality assessment step.

(Cusick *et al.*, 2009). In addition, various resources follow different curation guidelines, and therefore capture different information from the same publications. In the example complex, not all subunits may be supported by equally strong experimental evidence; different interaction databases may thus not agree on which interactions have been shown by the same experiment.

Incomplete Coverage

Despite the vast amount of data available, there are still very many genes and proteins about which we know surprisingly little. There are several reasons for this. First, a large percentage of genes are expressed only under specific conditions (e.g., in response to stress or during a specific developmental stage). The consequence is that so-called genome-wide studies in fact cover only the part of the genome that is expressed under the condition studied. Second, the biological systems are highly dynamic and their responses to internal and external stimuli can be transient and thus difficult to measure (Ideker and Krogan, 2012). Third, most experimental methods do not work equally well for all types of proteins. The available data

may thus be biased toward, for example, the most abundant proteins, proteins with specific physicochemical properties or proteins from certain cellular compartments (Jensen and Bork, 2008). In the protein complex example, the complex can be missed completely in a screen performed under conditions where one or more subunits are not present, or weakly attached subunits may not be found. Also, many assays, such as yeast two-hybrid, tend to miss membrane-associated complexes.

Data Quality and Heterogeneity

To gain systems-level insight into the regulation of biological processes, diverse types of data are required. However, the heterogeneous nature of the data makes them challenging to manage, analyse, and integrate, as they pertain to fundamentally different but interconnected biological questions, processes, and levels of regulation (e.g., genome, transcriptome, proteome, or interactome). For example, to study a protein complex in the context of a disease, the data collected may in addition to protein interactions cover single nucleotide polymorphisms (SNPs), copy number variations (CNVs), gene

expression signatures, protein abundance measurements, and posttranslational modifications, all of which need to be somehow integrated.

Even for a single type of data, different technological platforms have typically been developed (e.g., microarrays and RNA sequencing), which should be combined to get the most comprehensive view. However, the latter can be very challenging since the reliability of the data generated by the different technologies may vary considerably and be subject to different biases (von Mering *et al.*, 2002). Indeed, the quality can even vary between data points in a single dataset made using a single technology. In our example, the protein complex may have been studied by multiple different assays, such as yeast two-hybrid (Y2H) and affinity purification followed by mass spectrometry (AP-MS), and only a subset of the interactions found by either technology might be true.

Data Availability

A trivial obstacle to data integration is that you cannot integrate data you do not have. A common problem is that the data are not collected in databases or repositories; this is particularly often the case for new technologies for which standards have also not yet been developed. The only solution to that is unfortunately to extract that data from the backlog of articles and ensure that data are deposited in the future (Alsheikh-Ali *et al.*, 2011).

Even if a database exists, the data may not be available for integration. Some databases have restrictive licenses that forbid bulk download, redistribution, or commercial use (Freedman and Inglesse, 2014). Two major reasons for using such license are: to prevent competition from other research groups, to be able to commercialize the resource. Whatever the reason, licenses may make integration legally impossible or, more commonly, make it impossible to make integrated results available to others.

Another legal hurdle is the strict privacy laws that guard the access to genetics and healthcare data about individuals (Lunshof *et al.*, 2008). Although there are good reasons for these laws, one cannot deny that it makes integration of such data very complicated from a legal aspect.

Identification of Suitable Resources and Data Interpretation

Even when sufficient data are available, discovering the most suitable out of the hundreds of publicly available resources can be a daunting task. It is often assumed by the developers that the users already understand the type of data stored in the database and the methods used to analyze them. In addition, analyzing high-throughput data are commonly analyzed using sophisticated computational methods, without the user understanding the algorithms and their limitations. Consequently, the methods may be inappropriate for the input data type or the applications used may not respond the questions asked by the user.

Solutions

Nomenclature Systematization of Biological Entities

A very common strategy toward the standardization of heterogeneous data is the creation of naming standards

(Gelernter and Lesk, 2011; Philippi and Köhler, 2006). Nomenclature standardization efforts driven by the research community as the ones by the Human Genome Organisation (HUGO), Gene Nomenclature Committee (HGNC), or the various model organism databases ensure that each gene is assigned a unique approved name (Eppig *et al.*, 2005; De la Cruz *et al.*, 2005; Gray *et al.*, 2013). Similarly, many other efforts aim to standardize other biological entities and concepts with controlled vocabularies and ontologies (Blake and Bult, 2006).

A controlled vocabulary is defined by the collection of terms used to describe a specific scientific domain. Different nomenclature and annotation of the same entities obtained by the individual sources is linked to a predefined set of terms. For example, the UniProtKB database assigns 'keywords' to the different protein entries (Apweiler *et al.*, 2004). The user can make queries with keywords and find easily and fast a protein or a subset of proteins, based on specific biological features (e.g., function, structure, disease, domains, etc.). It is a very popular and highly emerging strategy, mainly used to resolve semantics ambiguities caused by synonyms, homonyms, etc., facilitating thus significantly the data exchange (Kelso *et al.*, 2003).

Ontologies, on the other hand, include controlled vocabularies, describing through the relationships between the different entities. While the definition of the term 'ontology' has its roots in philosophy, meaning the study of the 'being' or the 'existence,' in modern biology, ontologies are defined by the use of entity graphs, built to rather structure the knowledge and describe possible relationships between the represented entities in a hierarchical manner (Schuurman and Leszczynski, 2008; Blake and Bult, 2006). They are widely used in data integration approaches, as they can resolve natural language inconsistencies and enable interoperability between different resources, where unspecific description and annotation terms are used (Blake and Bult, 2006). Ontologies are designed with the use of specific languages, which are understandable by both humans and processing software. Maybe the most representative example of ontologies used in biology is the Gene Ontology (GO) project (The Gene Ontology Consortium, 2008). GO is a structured vocabulary of terms describing three aspects of gene functionality, namely biological process (BP), molecular function (MF), and cellular component (CC). GO is currently under the umbrella of the open biomedical ontologies (OBO) foundry between another 60 biology-related ontologies. This collaborative effort aims to coordinate ontologies by establishing common principles for their development, syntax, and interoperability features (Smith *et al.*, 2007).

Data Structure Standardization

As discussed above, the data standardization efforts aim at facilitating the data exchange and reusability. This is the responsibility both of the individual researchers creating datasets and of the developers who provide public databases to disseminate research results in as clear and usable a manner as possible. It is important that the data representation makes the data understandable and interpretable, which in addition to the data itself requires additional information about the data,

called metadata (Vempati *et al.*, 2014). Typical examples of metadata are when the data were generated, by whom, and with which technology. From an analysis standpoint more metadata is always better; however, since entering such information can quickly get very time consuming, so-called minimum information standards have been designed with the aim to collect the most important metadata, but not more. The first such standard was the minimum information about a microarray experiment (MIAME) (Brazma *et al.*, 2001). This has since been followed by minimum information standards for proteomics experiments (Orchard and Hermjakob, 2008), interaction studies (Orchard *et al.*, 2007), RNAi experiments (Shamu *et al.*, 2012), bioactive entities (Orchard *et al.*, 2011), flow cytometry (Lee *et al.*, 2008), and many more.

Text-Mining Approaches

As a response to the exponential growth of the scientific literature, nowadays, automatic text-mining is increasingly being used by the community in biomedical research to deal with the literature being too large for a human to curate (Rebholz-Schuhmann *et al.*, 2012; Zhu *et al.*, 2013). The two key steps in a typical biomedical text-mining pipeline are named entity recognition and information extraction. The first step involves recognizing the terms in the text that refer to entities or concepts of interest, for example, genes and diseases, and normalizing them to standardized names or identifiers. The second step is to extract relationships between them. An easy approach is to simply link entities to each other if they co-occur in the text. Despite its simplicity, this method can be surprisingly powerful when taking into account the number of times two entities co-occur. A much more advanced approach is natural language processing, which takes into account the syntax (structure) and the semantics (meaning of the words) of the text (Rodríguez-Esteban, 2009).

Computational Prediction Methods

The inherent limitations of current experimental techniques give a need for prediction methods to complement them. This is particularly needed because so many genomes are now being sequenced that experimental characterization of all the genes within them is unrealistic.

The most common approach, used by the individual researchers on a small scale and by various analysis tools in a systematic manner, is to make predictions by transferring functional annotation from homologous genes in different organisms (Dolinski and Botstein, 2007). In this context, it is important to distinguish between two classes of homologs: orthologs, which started diverging after a speciation event, and paralogs, which diverged after a gene duplication event. This distinction is essential when studying and predicting gene functionality, since the orthologs are more likely to have similar function across the organisms than the paralogs (Altenhoff *et al.*, 2012). The potential of using orthologs to predict function has motivated the development of a number of methods that aim at inferring orthology. Most of these methods can be classified in two types (Trachana *et al.*, 2011), namely graph-based methods (Powell *et al.*, 2014; Kristensen *et al.*, 2013; Waterhouse *et al.*, 2013) and tree-based methods

(Ruan *et al.*, 2008; van der Heijden *et al.*, 2007; Huerta-Cepas *et al.*, 2014).

Methods also exist for making predictions when homologous genes of known function cannot be found. Many such methods are based on machine-learning algorithms, such as artificial neural networks or support vector machines, to predict, for example, subcellular localization (Nakai and Horton, 1999; Briesemeister *et al.*, 2010), broad functional classes (Jensen *et al.*, 2003), or posttranslational modifications (Biswas *et al.*, 2010; Steentoft *et al.*, 2013; Blom *et al.*, 1999) from protein sequences. Various methods have also been developed to predict which proteins interact (Pazos and Valencia, 2001; Matthews *et al.*, 2001) or are functionally related from their evolution or genomic context (Hamp *et al.*, 2013; Michel *et al.*, 2014; Huynen *et al.*, 2000; Marcotte, 1999; Snel *et al.*, 2002).

Quality Assessment and Benchmarking

To integrate heterogeneous datasets of varying quality, it is important to assess the quality of each dataset and put them on a common scale. This can be achieved by quantifying how well they agree with a common reference set, often called the gold standard. This benchmarking process both reveals the relative quality of the datasets and provides a common scale, namely the agreement of a dataset with the gold standard (Qi *et al.*, 2006). However, because all parts of a dataset may not be of the same quality, such global benchmarking is typically not sufficient. This can be solved by developing a scoring scheme for each type of data, which allows the data points from a single dataset to be ranked by confidence. By calibrating these scores against the gold standard, it is possible to estimate the quality of each individual data point rather than for the dataset as a whole. This process converts all datasets to probabilistic scores that are directly comparable to each other and can be combined to provide experimental and prediction inferred information under a unified scoring scheme (Kuhn *et al.*, 2014; Warde-Farley *et al.*, 2010; Troyanskaya *et al.*, 2003; Franceschini *et al.*, 2013; Chen *et al.*, 2009). In addition, it enables the inclusion of all available data, even if they are considered as unreliable. Instead of just discarding low-confidence data, all data should ideally be taken into account and weighted according to its reliability.

Open Licenses

As discussed earlier, data availability can be an issue for data integration. In some cases the solution is obvious; if labor intensive: if the data have not already been gathered in a database, the only solution is that someone does so (Berman *et al.*, 2000; Barretina *et al.*, 2012; Chang *et al.*, 2013). However, in other cases a database exists, but its license stands in the way of it being integrated with other databases. In case of commercial databases, one option is obviously to develop a public alternative from scratch; an example of this is the PubChem Project (Wang *et al.*, 2009). However, in some cases it may be possible to instead transform a commercial resource into a public one. A notable example of this is the ChEMBL database (Willighagen *et al.*, 2013), formerly sold

as StARlite, which was made public with funding from the Wellcome Trust. License issues also exist for many databases created in academia. As the development of databases in academia is generally funded through grants, funding agencies like the National Institutes of Health (NIH) and Wellcome Trust increasingly require that the results of funded projects are made public to maximize their usefulness (Guttmacher *et al.*, 2009; Roche *et al.*, 2014). To make it clear that others can legally reuse the data as they see fit, this is typically done by mandating that the data are made either public domain or available under an open license such as the Creative Commons Attribution license.

Critical Thinking in Data Interpretation

For users to be able to properly use databases and other resources, it is important that developers document how the data stored in a resource were produced, curated, and analyzed. However, irrespective of whether this was done or not, users should apply the same critical thinking when interpreting the results from a bioinformatics resource that they apply when performing wet-lab experiments. In both cases, the researcher should ask a specific question and design controls. Consider a researcher who performs a typical case-control study, using mass spectrometry to identify significantly regulated proteins. If a statistical analysis tool shows that the regulated proteins are enriched for mitochondrial proteins, a good negative control would be to use the same tool to test if the same is true for the proteins identified as nonregulated. This would reveal if the regulated proteins are in fact enriched for mitochondrial proteins, or if this is likely an artifact of detection biases.

Conclusions

- Analyses of the huge amount of the biological data produced over the last years have it obvious that biological systems are far more complex than originally thought and that they cannot be understood one protein at a time.
- Applying systems biology approaches to cellular regulation requires integration of biological data representing multiple layers of regulation.
- The dimensionality, heterogeneity, and scattered nature of the biological data poses many challenges concerning data access, integration, analyzing, and interpreting the data.
- There is no single solution to addressing all the challenges. Important steps in the right direction include standardization of names and data formats, improving access to and licenses on data, text-mining of the scientific literature, and development of computational methods for data quality assessment and inference.
- Although we used examples from protein interactions throughout the article, the challenges and possible solutions to overcome them are general and apply to almost all types of high-throughput data, including genomics, transcriptomics, and proteomics data.
- Due to the complexity of many methods used in the field, controls and critical thinking is as important for computational experiments as it is in the wet lab.

A dramatic reorganization of the body of knowledge on cancer initiation, progression, and drug sensitivity has occurred over the last decade. This reorganization has been primarily driven by an explosion in the volume of molecular-level data, unquestionably resulting from the introduction of novel technologies for the cost-effective, high-throughput characterization of cancer cells' genetic, epigenetic, and functional landscapes. Such exponential data growth has required increasingly sophisticated analytical methodologies, ranging from the integrative statistical approaches, to complex machine learning methodologies for clustering and classification, to algorithms for the assembly and interrogation of cellular networks. Taken together, these approaches define the field of Computational and Systems Cancer Biology.

Development of gene expression profiling technologies, for instance, initially using microarray and more recently RNA sequencing platforms, has allowed fine-grain monitoring of RNA transcripts dynamics following tumorigenesis (Alizadeh *et al.*, 2000; Network, 2008; Hudson *et al.*, 2010) or following drug perturbation (Lamb *et al.*, 2006). Computational analysis of these profiles has helped elucidate molecularly distinct, yet morphologically indistinguishable cancer subtypes, associated with differential outcome (Phillips *et al.*, 2006), progression (Lossos *et al.*, 2002), and drug sensitivity (Barretina *et al.*, 2012). They have also helped identify key genetic programs that are consistently activated (e.g., proliferation, migration, and immuno-evasion), inactivated (apoptosis, senescence), or modulated (adhesion, angiogenesis, etc.) in tumorigenesis (Alizadeh *et al.*, 2000; Klein *et al.*, 2003). Collectively, these results have led us to better understand cancer as a highly heterogeneous disease, while also providing a molecular basis to study commonalities, such as sensitivity to targeted agents that are spanning across highly diverse tumors.

At the other end of the spectrum, genome wide studies of both heritable and somatic human variation have moved from theoretical concept to practical reality, thus opening a new window on both aspects of cancer etiology. Yet, even as the repertoire of recurrent germline and somatic alterations

increases in several tumor types, elucidating their mechanistic role in tumor-related phenotypes remains an overall elusive target.

Indeed, despite impressive algorithmic advances and large-scale data availability, the precise relationship between genetic alterations and dysregulation of cancer-related programs is still poorly understood and the precise cascade of molecular events leading to tumorigenesis and progression remains largely uncharted. For instance, while the mesenchymal subtype of glioblastoma represents a distinct and highly aggressive subtype, only relatively rare mutations in the NF1 gene (Verhaak *et al.*, 2010) and in CTNND2 (Frattini *et al.*, 2013) could be identified by association studies, and the mechanism by which NF1 drives the subtype has not been elucidated (Figure 1). Similarly, while large sequencing efforts have identified several mutations in the B cell receptor pathway that partially co-segregate with the more aggressive activated B cell (ABC) subtype of diffuse large B cell lymphoma, the same mutations can also be found in samples representing the more indolent germinal center B cell (GCB) subtype (Compagno *et al.*, 2009). Thus, while some tumor subtypes co-segregate with specific mutational landscapes (e.g., amplification of hormone receptors in luminal breast cancer), many tumors either lack subtypes entirely or have subtypes that fail to obviously co-segregate with tumor genetics. Similarly, tumor specific characteristics, such as sensitivity to specific targeted drugs or their indolent versus aggressive nature is not effectively predicted by the genetics, such as in prostate cancer (Taylor *et al.*, 2010) or in cell line sensitivity to targeted compounds (Barretina *et al.*, 2012). This suggests that, similar to complex heritable diseases, the relationship between genetics and cancer, with a few notable exceptions, may be too complex for standard association discovery approaches and may require more model-based approaches, as also discussed in (Califano *et al.*, 2012). Indeed, few epistatic interactions and low-penetrance variants have been identified so far in complex diseases (Narayanan *et al.*, 2010), mostly due to cohort size limitations (Manolio *et al.*, 2009) and lack of methodologies.

Figure 1 Genomic alterations in glioma co-segregate with only some of the identified molecular subtypes. Reproduced from Verhaak, R.G., Hoadley, K.A., Purdom, E., *et al.*, Cancer Genome Atlas Research, 2010. Integrated genomic analysis identifies clinically relevant subtypes of glioblastoma characterized by abnormalities in PDGFRA, IDH1, EGFR, and NF1. *Cancer Cell* 17 (1), 98–110.

The same is likely to occur in cancer, unless novel methodologies and study designs are introduced.

Integrative and Systems Biology Methodologies

To address these challenges, the computational and systems biology community has developed a variety of integrative and model-based methodologies. Integrative methods are frequently confused with systems biology ones, although they are driven by very different principles. Their value arises from the ability to combine partially or fully statistically independent evidence from diverse sources, for instance by combining functional evidence from gene expression profiles, as well as from genetic and epigenetic (henceforth genomic) mutational profiles. When independent evidences are combined, using methods such as Fisher's (Fisher, 1925), Stouffer's (Stouffer *et al.*, 1949), Naïve Bayes classifiers (Domingos and Pazzani, 1997), or Random Forest (Breiman, 2001), among others, overall statistical significance increases dramatically. This is a key when the number of testable hypotheses is so large that extremely low p -values are necessary to achieve statistical significance. Even when the evidences have partial dependencies, statistical integration methods such as Bayesian Networks (Pearl, 1985) or Brown's method (Brown, 1975) still produce important gains in overall significance.

In contrast, systems biology methods rely on an orthogonal approach to address the vast number of testable hypotheses. Rather than improving the statistical significance of the individual hypothesis by integrating multiple clues, they use biological models, such as regulatory network models, to eliminate the vast majority of testable hypotheses. The term 'regulatory network' has typically referred to the repertoire of physical interactions involved in regulating mRNA transcripts, including both transcriptional and posttranscriptional processes. In systems biology, however, the term is now used

more broadly to indicate any physical interaction affecting the abundance, chemical modification, or activity of a biomolecule, including some classes of causal indirect interactions. Within this broader acceptance, we will use the term to indicate transcriptional, posttranscriptional, posttranslational, and metabolic interactions, including protein–protein interactions in stable complexes. Regulatory network models can be represented using a variety of formalisms, from qualitative representation such as cancer pathways, to more quantitative models based on statistical regulatory dependencies or kinetic differential equations. Due to parametric complexity, the latter are generally restricted only to specific pathways, such as those controlling apoptosis or growth signals.

Given a regulatory model, a typical way to formulate questions using a systems biology approach (e.g., to identify cancer driver genes), is to compute the probability $p(G|M,D)$. This quantity represents the posterior probability that (G) is a driver gene or driver mutation, given a regulatory model (M) and a set of measurement data (D) produced by that model. This type of reasoning was originally introduced using the Bayesian formalism (Friedman, 2004) and has since been extended to a variety of additional methodologies (Schadt *et al.*, 2005; Carro *et al.*, 2010; Kwong *et al.*, 2012). While models of cancer cell regulation (henceforth *interactomes*) are still in their infancy, they are already providing significant new insight into cancer drivers and mechanisms. This is likely to improve significantly, as they become more accurate and comprehensive. A critical advantage of these approaches is that any inferred cancer-relevant gene-product or mutation is placed within a corresponding regulatory context. This is critically valuable, as such information can be harnessed to generate experimentally testable hypotheses about the mechanism by which these gene products and mutations affect cancer phenotypes, see (Chen *et al.*, 2014; Sumazin *et al.*, 2011; Carro *et al.*, 2010; Kwong *et al.*, 2012) for some representative examples. In contrast, while non-model-based approaches have helped identify a

Figure 2 Circos plot showing the whole-genome catalog of somatic mutations from the melanoma cell line COLO-829, including ~30 000 somatic base substitutions and ~1000 somatic insertions and/or deletions. 272 somatic substitutions are in exons, including 155 missense, 16 nonsense, and 101 silent mutations. The number and type of mutation are highly variable across different cancer genomes. Chromosome number and karyotype are indicated on the exterior of the plot. Key: blue lines, copy number across each chromosome; red lines, sites of loss of heterozygosity (LOH); green, intra-chromosomal rearrangements; purple, interchromosomal rearrangements; red, nonsense mutations; green, missense mutations; black, silent mutations; brown, intronic and intergenic mutations (merged). Reproduced with permission from Pleasance, E.D., Cheetham, R.K., Stephens, P.J., *et al.*, 2010. A comprehensive catalogue of somatic mutations from a human cancer genome. *Nature* 463 (7278), 191–196.

variety of driver genes and mutations, their inference is based on the analysis of statistical or complex machine learning based dependencies. These do not lend themselves to mechanism elucidation and validation. Indeed, statistical association are generally validated either by analysis of independent patient cohorts or by direct analysis of the phenotypic effects resulting from the experimental modulation of the gene or mutation of interest (e.g., using isogenic models), independent of mechanism.

These remarkable advances in integrative and systems biology approaches to the study of cancer, see (Pe'er and Hachohen, 2011; Werner *et al.*, 2014; Califano *et al.*, 2012) for some recent reviews, would not have been possible without the availability of molecular profiles representing distinct data modalities across a variety of human malignancies, as made available by The Cancer Genome Atlas (TCGA) (Network, 2008), the International Cancer Consortium (ICG) (Hudson *et al.*, 2010), and the Therapeutically Applicable Research To Generate Effective Treatments (TARGET) consortia (Mullighan *et al.*, 2009), among others. Indeed, these new methodologies are becoming increasingly valuable precisely because of the

overwhelming number of testable hypotheses resulting from direct statistical analysis of these resources.

This is arguably the key limitation of more traditional associative methods, such as those used in genome wide association studies (GWAS). Indeed, given the very large number of somatic events routinely discovered in cancer genomes, including mutations, translocations, gene fusions, aberrant copy number changes, and structural rearrangements (Stephens *et al.*, 2011), see Figure 2, distinguishing 'driver' from 'passenger' alterations is challenging and often impossible on a purely statistical basis. Thus, not surprisingly, the tumors where most causal alterations were originally elucidated are those with the least complex mutational landscapes, such as leukemias and lymphomas. The problem only becomes more complex when broader genomic modalities from epigenetic profiles to extracellular signals are considered or, even worst, when epistatic or synergistic combinations are considered (i.e., pairwise combinations of genomic alterations).

Rather than being antithetic, integrative and systems methods are often used in combination, resulting in significant contributions to the elucidation of key genetic drivers in

Figure 3 The ‘Omics layer of the cell both encode and are processed by a context-specific regulatory logic. At the atomic level, this logic is implemented via molecular interactions, such as protein–DNA, protein–protein, protein–RNA, RNA–RNA, etc. Dissection and interrogation of this logic in context specific fashion, using systems biology approaches, allows for elucidating driver genes responsible for the presentation of relevant cancer-related phenotypes.

cancer and other diseases (Califano *et al.*, 2012). The rationale for these methods is that interactomes, representing causal molecular interactions in the cell help pinpoint candidate driver gene(s) within genetic programs that are dysregulated in cancer. These can then be experimentally validated as either individual (Chudnovsky *et al.*, 2014; Della Gatta *et al.*, 2012; Zhao *et al.*, 2009; Compagno *et al.*, 2009; Palomero *et al.*, 2006; Taylor *et al.*, 2010; Network, 2008) or synergistic/co-operative (Aytes *et al.*, 2014; Carro *et al.*, 2010; Kwong *et al.*, 2012) drivers of tumor-related phenotypes, including genes harboring causal genomic alterations in populations (Chen *et al.*, 2014; King *et al.*, 2009) and even within individual tumors (Ding *et al.*, 2010), see Figure 3.

The use of regulatory models for the causal association of heritable or somatic variants to gene expression patterns (i.e., genetical genomics) was originally pioneered in plants (Schadt *et al.*, 2003) and metabolic disease (Yang *et al.*, 2009). Yet, more recently they have been used successfully in neurodegenerative phenotypes (Zhang *et al.*, 2013) and cancer (Chen *et al.*, 2014; Zhao *et al.*, 2009; Della Gatta *et al.*, 2012; De Keersmaecker *et al.*, 2010). For instance, identification of the novel HUWE1-MYCIN-DLL3 cascade in brain tumors, where HUWE1 is frequently deleted, was possible by reverse engineering posttranslational modulators of MYCN activity as well as its downstream targets using reverse engineering algorithms (Zhao *et al.*, 2009). Similarly, the role of RUNX1 as a tumor suppressor, harboring frequent mutations in T-cell acute lymphoblastic leukemia (T-ALL) (Della Gatta *et al.*, 2012), was elucidated based on the overlap of its regulatory program with those of TLX1 and TLX3, two previously established oncogenes (De Keersmaecker *et al.*, 2010). In some cases, molecular-level

understanding of regulatory events may allow elucidating dependencies between a phenotype and a repertoire of genetic events, which could be identified by statistical approaches on an individual basis. For example, deletion of any combination of 13 genetic loci distributed across the entire genome leads to functional inactivation of PTEN in glioma patients, via the recently proposed competitive endogenous RNA (ceRNA) mechanism (Sumazin *et al.*, 2011). Yet none of these events would be individually significant, either functionally or statistically. Use of regulatory or dependency models, ranging from graphical models to fully detailed kinetic models, has exploded over the last 5 years, with applications ranging from the study of key drivers of tumorigenesis in melanoma (Kwong *et al.*, 2012; Akavia *et al.*, 2010), glioma (Chudnovsky *et al.*, 2014; Chen *et al.*, 2014; Sumazin *et al.*, 2011; Carro *et al.*, 2010; Sonabend *et al.*, 2014), leukemia/lymphoma (Piovan *et al.*, 2013; Della Gatta *et al.*, 2012; Compagno *et al.*, 2009), and prostate cancer (Ergun *et al.*, 2007; Aytes *et al.*, 2014), as well as across multiple tumor types (Mendillo *et al.*, 2012; Vaske *et al.*, 2010; Csibi *et al.*, 2013), to the dissection of oncogenic tyrosine kinase signals (Yarden and Pines, 2012; Schoeberl *et al.*, 2009; Kirouac *et al.*, 2013; Albeck *et al.*, 2013; Tentner *et al.*, 2012; Wagner *et al.*, 2013), and the characterization of drug activity (Komurov *et al.*, 2012), off-target effect (Chang *et al.*, 2010), and synergy (Lee *et al.*, 2012; Nelander *et al.*, 2008; Bansal *et al.*, 2014; Piovan *et al.*, 2013).

Other classes of model-based approaches are also emerging that are not based on molecular interactions. For instance, several studies have highlighted the ability to model properties of the tumor, such as growth and response to

radiotherapy, in terms of competition of distinct cellular subpopulations (Marusyk *et al.*, 2014; Leder *et al.*, 2014; Haeno *et al.*, 2012).

Assembly and Analysis of Cancer Regulatory Models

As discussed, the availability of increasingly accurate, comprehensive, and cell-context-specific interactomes will be critical to the success of model-based systems biology. In particular, it has been shown that interactomes are highly predictive only when they are representative of the specific context of interest (Aytes *et al.*, 2014). This is because epigenetic reprogramming of the cell during lineage differentiation, combined with differential availability of cofactors, results in molecular interactions that are broadly dependent on tumor cell context. As a result, reverse engineering of tumor specific interactomes, whether using experimental, computational, or hybrid approaches, represents a defining challenge in cancer systems biology. Ultimately, however, we expect that these efforts will help transition from cancer pathway based (Wang *et al.*, 2010) to regulatory network-based discovery (Califano *et al.*, 2012).

Cancer pathways represent a coordinated effort to 'linearize' molecular interactions to make them intuitively accessible to the biologist, via a relatively simple graphical representation. Such an effort, however, is ultimately doomed because the true complexity of biological interactions – including hundreds of thousands of signaling, transcriptional, protein-complex, small noncoding RNA, and metabolic interactions – simply does not lend itself to such a simplistic representation. In addition, cancer pathways are presented as intrinsically universal structures rather than as tumor specific ones. For instance, in its canonical representation (see Figure 4(a)), the

epidermal growth factor receptor (EGFR) pathway would appear as virtually identical in all tumor contexts, which is clearly not the case. Not surprisingly, a prior hypothesis being absent, pathway-based approaches have been largely unsuccessful in the elucidation of novel tumor-related mechanisms.

To better appreciate the difference, compare Figure 4(a), showing differential phosphorylation of canonical EGFR pathway proteins in the H1650 cell line, where EGFR harbors an activating mutation, versus EGFR wild type cell lines to Figure 4(b), showing the same differential phosphorylation pattern on a signaling network, inferred *de novo* from phosphopeptide profile data of a large collection of lung adenocarcinoma samples (Rikova *et al.*, 2007). While the pathway-based representation provides no clue that the EGFR pathway may be dysregulated, the network-based representation shows hyper-phosphorylation of virtually all EGFR, EPHA2, and TNK2 predicted substrates, with EGFR predicted as the single most aberrantly signaling tyrosine kinase, based on statistical significance.

In cancer, systems biology approaches have now evolved to include the following 3 steps. First, acquisition of complementary molecular profiles is performed, including transcriptomic, mutational, epigenetic, proteomic, and metabolomic modalities. This data is then used to reconstruct associated interactome models. Finally, these are interrogated using genetic and genomic signatures representing the cellular states of interest. We will discuss the two latter steps in more detail.

Interactome Reverse Engineering

Cell behavior is determined by the processing of endogenous and exogenous signals by the machinery that is in charge of maintaining cellular homeostasis and to make critical decisions

Figure 4 (a) Pathway-based representation of differential EGFR pathway protein phosphorylation in H1650 cells, harboring an EGFR activating mutation. Proteins tagged with a red circle are hyper-phosphorylated, those tagged with a green circle are hypo-phosphorylated, and those with an orange circle are unchanged. Phosphopeptide abundance for the remaining proteins was not detected. (b) Network-based representation of differential protein phosphorylation in H1650 cells. The signaling network was inferred *de novo* from a large phospho-proteomic dataset (Rikova *et al.*, 2007) for lung adenocarcinoma. Proteins are shown as either Red (hyper-phosphorylated), green (hypo-phosphorylated), and yellow (unchanged). Individual substrates associated with EGFR, EPHA2, and TNK2 are shown, as the three most enriched in phosphorylated substrates. Substrates are associated to phosphorylation of specific tyrosines on the corresponding kinases (e.g., Y1197 on EGFR).

in the presence of specific signals, for example, activating apoptosis when p53-mediated DNA damage repair is unsuccessful or senescence when oncogenic KRAS signals are detected. This machinery is implemented through a complex network of molecular interaction, i.e., the interactome, comprising several cross-interacting layers. Among the principal categories, these represent transcriptional, posttranscriptional, signal transduction, protein-complex, and metabolic interactions.

Disruption of interactome topology or dynamics by genomic events, either within a layer or across layers, can reprogram the cell by activating aberrant programs and ultimately leading to tumorigenesis. For instance, abrogating the regulatory program controlling expression of the MYC proto-oncogene by translocation is a key event in lymphomagenesis, while overexpression of the estrogen receptor by gene duplication events constitutes a key event in breast cancer tumorigenesis. Cancer systems biology is predicated on the simple premise that the logic of regulatory models can be ‘reverse engineered’ from experimental data – from simple kinetic models describing a handful of genes to probabilistic models of genome wide regulation – to help elucidate these aberrant events.

Over the past decade, multiple strategies have been developed for the *de novo* reverse engineering of regulatory models of mammalian cells, even though the first methods were driven for the study of yeast and bacteria, as simpler model organisms (Friedman, 2004; Gardner *et al.*, 2003; Tavazoie *et al.*, 1999). A key advantage, in the latter, is that genomic regulatory regions are relatively short, allowing the efficient use of sequence information to infer the cell regulatory logic. For instance, yeast promoter regions are 600 bp on average, thus allowing straightforward analysis. In comparison, distal regulatory elements in human genes can be hundreds of kilobases away from transcription start sites. In addition, gene regulation in higher eukaryotes is made even more complex by alternative splice variants, alternative start sites, and multiple poly-A tails.

Fortunately, despite these challenges, data availability and more sophisticated computational algorithms have significantly improved our ability to reverse engineer mammalian regulatory models more accurately and comprehensively. These methodologies can be roughly divided into the four categories discussed below.

Optimization Driven Machine Learning Approaches

Due to the multivariate nature of cellular regulation and to the relatively small number of distinct molecular profiles available in tumor repositories, classical machine learning based methods, such as maximum likelihood (ML), cannot be effectively applied to inferring causal regulatory relationships. However, several heuristics, such as maximum parsimony, have improved their applicability (Larranaga *et al.*, 2006). A standard approach in ML is to ask ‘What is the regulatory model that maximizes the posterior probability of having produced the observed molecular profile data?’ This cannot be addressed by brute-force enumeration of all possible models. As a result, greedy algorithms and associated approximations have been developed, such as assuming that regulatory models can be represented as directed acyclic graphs (DAG), without feedback loops (Friedman, 2004). The highest probability

model can then be used to predict behavior based on independent data (Larranaga *et al.*, 2006). Examples of such methods include the analysis of regulators of gene expression modules (Segal *et al.*, 2003), as well as the use of Bayesian and Dynamic Bayesian Networks for reverse engineering transcriptional (Friedman, 2004; Hartemink, 2005) and signal transduction networks (Sachs *et al.*, 2005). For a review of these methods, see (Andersson *et al.*, 2011; Ezkurdia *et al.*, 2009; De Vries and Bonvin, 2008). Factors that affect the precision of the predictions by ML approaches include the dataset quality, feature preselection for single residues, and algorithm selection based on the purpose and data type (Franke *et al.*, 2012).

Integration of Prior Knowledge and Experimental Evidence

Rather than predicting interaction from a single data modality, for example, from gene expression profile data, systems biologists have embraced the vast number of repositories containing experimental data from high-throughput approaches. These range from gene expression profile, to genome wide Chromatin Immunoprecipitation data (GW-ChIP), to yeast-two-hybrids and nuclear pull down assays. Albeit partial and often inaccurate in isolation, the knowledge contained in these repositories can be effectively integrated into a single unified model, using computational approaches to combine the probability of a specific molecular interaction. For instance, prediction of transcriptional interactions may integrate data from GW-ChIP, DNA binding site motif analysis, and co-expression, among others. The use of machine learning frameworks for the integration of multiple weak clues, from Naïve Bayes Classifiers (Lefebvre *et al.*, 2010), to Bayesian Networks (Jansen *et al.*, 2003), to a variety of consensus scoring methods, has been very successful in generating more accurate and comprehensive molecular interaction models (42, 43). Recently, intriguing observations have been published by the Dialog on Reverse Engineering Assessment Methods (DREAM) consortium (Marbach *et al.*, 2012). DREAM is an attempt to objectively measure the ability of computational approaches to correctly infer facts about regulatory network structure. Specifically, it was shown that integration of results from multiple inference algorithms performs better or at least as well as the best individual algorithm. This is an important result, as we often do not have a principled approach to objectively assess the quality of each given method and may instead want to use the integrative results of several of them. An additional value of integrative methods is that they allow seamless integration of heterogeneous data. For instance, it was recently shown that protein structure information, from X-ray and NMR crystallography, can be effectively integrated with functional data to accurately predict protein–protein interactions (Zhang *et al.*, 2012). For a more comprehensive review of integrative approaches, see (Bebek *et al.*, 2012).

Regression Analysis

Regression techniques have long been used to estimate parameters for kinetic models from experimental data and could,

at least in theory, be extended to the inference parameters for entire regulatory models. Various regression methods have been proposed for pathways or network inference, including ML (Lyles *et al.*, 2012; Knott, 2005), least squares (LS) (Li *et al.*, 2011, 2012; Li and Gui, 2004), and Bayesian Inference (BI) (Sarder *et al.*, 2010; Jin *et al.*, 2012; Zhang *et al.*, 2011), to obtain estimates of model parameters (Jaqaman and Danuser, 2006). ML approaches infer parameter values from a distribution, as those maximizing the posterior probability of the experimental data; LS approaches determine the parameter values that minimize the sum of the squares of the residuals, i.e., the difference between each experimental and model-inferred datapoint; finally, BI methods use a priori models for the unknown parameter distribution to compute their most likely values. A key problem of regression methods is that they are generally under-determined, i.e., they have more parameters whose value must be inferred than independent observations. When this happens, an infinite number of parameter combinations produce an identical solution, thus requiring additional heuristics for selecting a specific set of values (e.g., equivalent to fitting a line through a single point). This is a common issue in real biological systems, as the number of parameters for a system with tens of thousands of interacting molecular species can be in the several hundred thousands but few datasets with more than a few hundred independent experimental profiles are available for the same system. To address this problem a number of dimensionality reduction approaches have been developed, which work by either splitting a single high-dimensional problem into a number of independent lower-dimensional ones, for example, via singular value decomposition (Yeung *et al.*, 2002), or by penalizing models with larger number of connections via sparsity constraints (Yeung *et al.*, 2002).

Information Theory and Probabilistic Methods

Shannon's information theory provides a useful probabilistic framework to study the flow of information in a complex system (Shannon, 1948). In recent years, information theory has become a staple of systems biology approaches (Waltermann and Klipp, 2011), for instance by predicting the minimal machinery in the cell necessary to account for the globally observed information transfer between distinct molecular species characterized by a profile, such as mRNA (Basso *et al.*, 2005; Wang *et al.*, 2009b; Goodarzi *et al.*, 2012), mutational data (Drees *et al.*, 2005), and microRNAs (Elemento *et al.*, 2007; Sumazin *et al.*, 2011). In general, these approaches try to assess the minimal set of interactions that must be in place to justify the observed flow of information, including either 2-way information, i.e., mutual information (MI) (Steuer *et al.*, 2002), or higher-order multivariate information, for example, conditional mutual information (CMI), multi-information, etc. (Wang *et al.*, 2006), thus allowing dissection of signaling or transcriptional interactions. MI measures the mutual dependence of two random variables, without any linearity assumptions (e.g., between the mRNA of a transcription factor and one of its potential targets). CMI measures whether the information transfer between two variables is dependent on a third variable, for instance the availability of a

protein kinase affecting the ability of a transcription factor to regulate its targets. Various probabilistic and information theoretic methods have been proposed for the reverse engineering of regulatory networks, some of which have been extensively validated, such as ARACNE (Margolin *et al.*, 2006; Basso *et al.*, 2005), MINDy (Wang *et al.*, 2009b), Hermes (Sumazin *et al.*, 2011), minet (Meyer *et al.*, 2008), and CLR (Faith *et al.*, 2007), among others.

ARACNe and MINDy, a Case Study

These two algorithms are among those that have been most extensively validated, allowing reverse engineering of networks that have led to a number of novel discoveries in cancer biology. We will thus use them as a self-contained case study to illustrate several relevant concepts in the area of reverse engineering. Other examples of validated algorithms with applications to the study of cancer and other disease include CONEXIC (Akavia *et al.*, 2010), CLR (Kwong *et al.*, 2012), and Bayesian Networks (Yang *et al.*, 2009; Sachs *et al.*, 2005), among others, see (Pe'er and Hachohen, 2011; Califano *et al.*, 2012) for a more detailed review.

ARACNe (Algorithm for the Reconstruction of Accurate Cellular Networks) has been widely applied to dissect transcriptional regulatory networks from gene expression profiles of multiple cancer subtypes, including B cell lymphoma (Basso *et al.*, 2005, 2010), glioma (Carro *et al.*, 2010; Sonabend *et al.*, 2014; Chudnovsky *et al.*, 2014; Zhao *et al.*, 2009), prostate cancer (Aytes *et al.*, 2014), T-ALL (Piovan *et al.*, 2013; Della Gatta *et al.*, 2012; De Keersmaecker *et al.*, 2010; Palomero *et al.*, 2006), and breast cancer (Lim *et al.*, 2009). ARACNE first hypothesizes candidate interactions between a transcription factor and a target gene ($TF \rightarrow T$) whose MI is statistically significant, when computed from their gene expression across a large number of experiments. Finally, candidate interactions that violate the Data Processing Inequality (DPI) are removed. The DPI states that information transferred via direct interactions always exceeds information transferred via indirect paths. Thus, if any indirect path ($TF \rightarrow TF_x \rightarrow T$) exists, with MI greater than the candidate direct interaction ($TF \rightarrow T$), then the direct interaction is removed. ARACNE was experimentally validated by ChIP and GW-ChIP assays, as well as by silencing of transcription factors followed by gene expression profiling, see above referenced manuscripts.

This type of analysis was extended to higher-order interactions. Specifically, the Modulator Inference by Network Dynamics (MINDy) algorithm (Wang *et al.*, 2009b), most recently refined to its true theoretical implementation (Giorgi *et al.*, 2014), was developed to identify posttranslational modulators of transcription factor activity on their targets using the conditional MI (Wang *et al.*, 2009a,b). These include both co-transcription factors and upstream signaling proteins regulating the transcription factor activity (Wang *et al.*, 2009b). Genome wide search based on this methodology were successful in identifying the HUWE1 ubiquitin ligase as a key modulator of MYCN in neural stem cells (Zhao *et al.*, 2009), the serine threonine kinase STK38 as a key modulator of MYC in human B cells (Bisikirska *et al.*, 2013), and the ubiquitin ligase adapter protein KLHL9 as a modulator of CEBPB and

CEBPD in the mesenchymal subtype of glioma (Chen *et al.*, 2014), among several other interactions that were experimentally validated.

Benchmarking Predictive Models

As exemplified in the previous section, the accuracy of interactome reverse engineering can be validated with careful testing of its predictions. However, the fast and relentless progress of technology to probe larger amounts of data and deeper layers of cellular organization create the need for an entire spectrum of algorithms to extract actionable information from the data. Predictions resulting from these methods, however, are infrequently validated experimentally and their objective value remains elusive. Thus systematic validation is important not only for interactome inference but also for virtually every other area of computational systems biology. Take, for example, the case of identification of somatic mutations in cancer biopsies, which is one of the valuable pieces of information needed to implement precision medicine. Recent studies have shown that when different researchers apply their algorithms to the same genomic data their results may be significantly discordant (Kim and Speed, 2013; O'Rawe *et al.*, 2013; Alkan *et al.*, 2011). Similar problems are found when comparing methods to reverse engineer gene regulatory networks (Marbach *et al.*, 2010) and signaling networks (Prill *et al.*, 2011).

The need to determine the accuracy of novel algorithms through an objective evaluation process, as well as to compare the relative merits of disparate methods designed to perform the same tasks has given rise to a relatively new modality of method assessment in the form of scientific competitions or Challenges (Costello and Stolovitzky, 2013). While there are several such efforts in different areas of bioinformatics (Boutros *et al.*, 2014) there are only a few such efforts in the field of systems biology, notably CAGI (Critical Assessment of Genome Interpretation) and DREAM (Dialog for Reverse Engineering Assessment and Methods) (Stolovitzky *et al.*, 2007). Typically these Challenges pose specific questions (e.g., inference of biological networks (Stolovitzky *et al.*, 2009), computational prediction of drug sensitivity (Costello *et al.*, 2014), and prediction of patient survival (Margolin *et al.*, 2013), among many others, which require integrative/systems analysis of vast amounts of data. Challenge participants train their algorithms from a provided dataset (training set), and make predictions that are blindly compared against an independent dataset they have no access to (testing set), used as a gold standard for validation. Using the latter, Challenge organizers can evaluate the methods while making a fair comparison of their strengths and weaknesses. From the perspective of the participants, the experience is not unlike real-world problems, in which a method developer makes predictions and seeks experimental validation in novel scenarios.

Besides the merits of benchmarking and method comparison, DREAM Challenges also aim at promoting research in novel areas (e.g., computational predictions of drug interactions in cancer cells (Bansal *et al.*, 2014)), accelerating discovery by crowdsourcing, assessing the computational tractability of biological problems, creating collaborative

communities, and, as discussed earlier, tapping on the wisdom of crowds as a robust solution for biological predictions (Marbach *et al.*, 2012).

Interrogating Pathways and Networks

Once regulatory models, such as pathways and networks are available, machine learning approaches can harness them to study cancer phenotypes. For example, a random forests algorithm was used to perform pathway-based single nucleotide polymorphism (SNP) analysis to predict cancer patient survival outcome (Pang *et al.*, 2011). Applied to multiple myeloma, using Affymetrix 500 K SNP array data, the method connected informative SNPs and patient survival, thus identifying candidate pathway involved in modulating patient survival and associated genetic variants (Pang *et al.*, 2011). A multitude of other machine learning algorithms have also been used to assist in GWAS analysis, such as SNP discovery (Wegrzyn *et al.*, 2009; Matukumalli *et al.*, 2006), SNP interaction (Ueki and Tamiya, 2012; Cheng *et al.*, 2012), cancer subtype classification (Wong *et al.*, 2012), survival outcome association (Van Ness *et al.*, 2008), and key genetic variant identification (Han *et al.*, 2010; Yu *et al.*, 2007), see (Szymczak *et al.*, 2009) for an more comprehensive review. Yet, a common characteristic of these approaches is that the associations they identify are statistical in nature and do not provide insight into mechanism. As a result, elucidation of the mechanism by which a somatic or germline variant regulates the corresponding tumor phenotype often substantially lags after its discovery by statistical analyses.

Several approaches are emerging to simultaneously address the reconstruction of context specific cell regulatory models and their interrogation for the identification of drivers of both physiologic and pathologic phenotypes, see (Califano *et al.*, 2012; Pe'er and Hacohen, 2011) for a more comprehensive review. For instance, the Master Regulator Inference algorithm (MARINA), see Figure 5, was used to computationally discover genes and associated mechanisms that are causally related to the implementation of a specific phenotype (Lefebvre *et al.*, 2010; Carro *et al.*, 2010; Lim *et al.*, 2009; Chudnovsky *et al.*, 2014; Aytes *et al.*, 2014), followed by their experimental validation. Rather than asking which genes are differentially expressed in a cancer phenotype, MARINA uses analyzes interactomes inferred by ARACNe or by other methods to identify candidate master regulator (MR) genes, whose transcriptional targets co-segregate with differentially expressed genes. Experimental validation assays are then used to identify those that are both necessary and sufficient for phenotype presentation. This approach was used, for instance, to elucidate CEBPB/CEBPD and STAT3 as synergistic master regulators of the mesenchymal subtype of human glioblastoma (Carro *et al.*, 2010), FOXM1 and MYB as MRs of the germinal center reaction (Lefebvre *et al.*, 2010), FOXM1 and CENPF as synergistic master regulators of the most aggressive subtype of prostate cancer (Aytes *et al.*, 2014), and ZFX4 as a master regulator of the NuRD complex in gliomagenesis (Chudnovsky *et al.*, 2014).

Similarly, different integrative network-based systems biology approaches were used to identify drivers of tumor initiation (Akavia *et al.*, 2010) and differential patient survival (Kwong *et al.*, 2012) in melanoma and glioma (Chen *et al.*, 2014).

Figure 5 Discovery of Master Regulator Genes using the MARINA algorithm. Master Regulators (e.g., R_1) are genes whose activated and repressed transcriptional targets are statistically significantly enriched in over and under expressed genes in the transition, respectively. Other regulators (e.g., R_n) have targets that are not enriched in differentially expressed genes.

While these constitute very recent developments, the availability of methods to assemble accurate and cancer specific regulatory models will determine an explosion in these kind of approaches.

Recent Trends and Future Perspective

As discussed above, a variety of research strategies have emerged in cancer systems biology since the discipline's conceptual inception, about a decade ago (Kitano, 2002; Ideker *et al.*, 2001). While the initial forays in this area were mostly of a theoretical nature, over the last 5 years these approaches have achieved significant success and gained considerable traction, especially in the elucidation of complex, multi-gene mechanisms that would not have been approachable using conventional molecular biology strategies. In its coming of age, systems biology has become one of the most powerful methods for the high-throughput generation of testable hypothesis, frequently achieving a greater than 50% likelihood of experimental validation, something that would have been previously unthinkable from purely computational approaches. For instance, validation of transcription factor targets, microRNA targets, and protein-protein interactions predicted by reverse engineering methods is frequently in the 80% range, thus competitive with high-throughput experimental approaches (Zhang *et al.*, 2012; Sumazin *et al.*, 2011; Wang *et al.*, 2009b; Basso *et al.*, 2005). Similarly, a number of disease mechanism have been recently elucidated, following validation of regulatory network-based predictions (Califano *et al.*, 2011; Yang *et al.*, 2009; Schadt *et al.*, 2005; Della Gatta *et al.*, 2012; Bisikirska *et al.*, 2013; Lefebvre *et al.*, 2010; De Keersmaecker *et al.*, 2010; Carro *et al.*, 2010; Zhao *et al.*, 2009; Pe'er and Hacohen, 2011; Konig *et al.*, 2010; Mendillo *et al.*, 2012; Kwong *et al.*, 2012; Komurov *et al.*, 2012). These are only a few representative examples from a now rapidly growing literature.

In spite of these successes, concerns and skepticism is still pervasive in the biological community on the role and effectiveness of systems biology approaches in dissecting complex diseases, such as cancer, and in elucidating novel therapeutic strategies for translational research. To address these concerns, this nascent discipline requires progress on two critical aspects: first, novel technologies that produce experimentally validated, biologically relevant results are critically needed; more importantly, translation of concepts emerging from systems approaches must lead to clinical applications.

While the genomic framework for the study of biology has now been around for over 20 years, its translational applications have only started to emerge in earnest over the last 5 years, largely as a result of the large amount of genomic information accumulated following completion of the human genome map. Systems biology and its applications to cancer are much more recent. As such, it would be unreasonable to expect immediate translation of its discoveries. Similar to genomics, this discipline will not achieve its true potential until appropriate datasets and technologies become available. The first attempts to translate cancer systems biology discoveries are only now starting to be tested in the clinic and several more years may be necessary before a compelling argument for clinical applications of systems biology may be made.

Drug Targeting – An Introduction

Imming *et al.* (2006) described a drug target as a molecular structure that will undergo a specific interaction with chemicals, termed ‘drugs.’ Drugs are so called because they are administered to treat or to diagnose a disease. At the time it was estimated that potentially thousands of these drug targets exist. Here we describe the evolution of the theories and experiments that have already been used to identify hundreds of these drug targets and those likely to underpin drug target identification efforts now and in the future.

A Historical Perspective

The concept of drug targeting was first postulated by Paul Ehrlich in the late nineteenth century upon noting the selective affinity of chemical dyes for specific biological tissues. Ehrlich thus proposed the idea of ‘chemoreceptors,’ whereby certain receptors on microorganisms or cancer cells, for example, would be different from analogous structures in host tissues, and that this difference could be targeted therapeutically (Drews, 2000). By the early twentieth century John Langley had proposed a more functional theory whereby receptors serve as a ‘switch,’ accepting signals and subsequently generating biological effects. These effects could thus be blocked by chemical antagonists or activated by chemical agonists (Drews, 2000; Pina *et al.*, 2009). These theories, and their subsequent iterations and evolutions, led to the development of the first rational synthetic drug, arsphenamine, a treatment for syphilis, in 1910. In addition these studies laid the foundations for the basic discovery process, where chemical libraries are screened for their biological activity, still utilized today (Bleicher *et al.*, 2003).

Over the course of the twentieth century this idea that one disease can be treated with one compound targeting one receptor has led to previously unprecedented therapeutic triumphs (Drews, 2000). The most successful of which are a class of compounds known as statins, which lower cholesterol levels by inhibiting the enzyme HMG-CoA reductase (Torbert, 2003). However, we now know that cells and organisms are not composed of linear pathways, and are instead complex nonlinear systems comprising highly interconnected networks (Baxter *et al.*, 2013). It is thus becoming increasingly important to view drug targeting from a network perspective in addition to more traditional approaches.

From Molecules to Systems

Systems biology was initially at the heart of drug discovery, whereby herbal or traditional remedies, usually extracted from plants, were discovered through anecdotal, albeit direct, observations in people with disease (Butcher *et al.*, 2004).

Of course the advent of chemistry and the subsequent leaps in understanding with regards to how drugs function has made direct observations of this type impossible. However, the completion of the Human Genome Project at the beginning of the twenty-first century (International Human Genome Sequencing Consortium, 2001) kick-started the development of large-scale data generating tools typically referred to as the ‘omics revolution,’ a combination of genomics, proteomics, and metabolomics. These tools, along with advances in imaging technologies, such as high-content screening, which enable the generation of high throughput, phenotypic data, have facilitated the rise in the role of modern systems biology in drug targeting. The aim of modern systems biology is thus to describe both physiology and disease over multiple hierarchical levels of interaction from molecules, to networks, cells, tissues, and eventually organisms (Butcher *et al.*, 2004).

Genomics in Target and Drug Discovery

The sequencing of the human genome, and those of other organisms, has led to the identification of many sequence variations, i.e., mutations, which could in turn lead to the identification of many new drug targets in various diseases (Kramer and Cohen, 2004). A primary role of genomics therefore is to better analyze and understand this knowledge in order to identify the critical variants and thus identify the best potential therapeutic targets. To this end, genomics data can be used to investigate the functional consequences of these variations in DNA sequence and gene expression (Emilien *et al.*, 2000; Kramer and Cohen, 2004). The most commonly used tool for determining gene expression is transcriptomics, which measures the mRNA transcripts produced in a cell or tissue system of interest. However, the major limitation of these studies is the poor correlation between mRNA levels and protein levels (Greenbaum *et al.*, 2003; Vogel and Marcotte, 2012). One of the reasons for this discrepancy is that mRNA (and protein) levels are dynamic, whereas most studies are static, i.e., measurements are taken at a single timepoint. Thus the changes observed do not necessarily represent the underlying signaling networks, which are predominantly driving the phenotype. With that said, transcript data has proven to be useful for classifying samples and has been shown to provide predictive information regarding patient outcome in cancers of the breast, brain, prostate, lymphoma, and leukemia (Ciro *et al.*, 2003).

One powerful experimental method for linking genomics to phenotype is phenotypic screening in combination with RNA interference (RNAi). RNAi takes advantage of naturally occurring mechanisms for gene regulation present in all cells, which results in the cleavage of messenger RNA, thus preventing translation of the protein. This can be combined with high throughput, and/or high-content, screening to discern the effect of inhibiting gene expression on *in vitro* or *ex vivo* disease models allowing researchers to identify direct, causal links

between genes and phenotypes (Krausz and Korn, 2008). As such, since its discovery, RNAi has become one of the most important functional genomics tools available, and has been utilized extensively in target identification and validation studies (Krausz and Korn, 2008; Lindsay 2003; Sachse *et al.*, 2005).

PCSK9, an Example of Drug Targeting in the 'Omics'-Era

A particularly interesting example of the power of genomics to deliver new drug targets is the story of PCSK9 a novel target for the treatment of cardiovascular disease, the leading cause of death worldwide.

A typical strategy for the identification of the genetic factors responsible for disease is the 'common variant hypothesis' which is based upon the theory that a handful of disease causing genes will be common enough to identify in genome-wide surveys of large populations (thousands) of people. However, in the case of cardiovascular disease this strategy has had limited impact, as whilst many common genetic variants have been identified, each only has a small effect on disease (Hall, 2013). Instead, scientists at the University of Texas Southwestern Medical Center took the opposite approach. They reasoned that Mendelian disorders, i.e., those caused by a single gene, do not typically arise from a single common mutation as this would most likely be removed through the process of natural selection. Instead they suggested that these sort of diseases are caused by one of a number of rare mutations, acting individually or cumulatively, but each resulting in the same disease phenotype (Hall, 2013).

Indeed a key aspect of the discovery of PCSK9 was the combination of phenotypic observations with genomic explanations. Phenotypic studies were first employed to group people based on their cholesterol levels. Then, the DNA of study participants was sequenced in order to identify the aberrant genes driving the disease phenotype. It was found that PCSK9, depending on the mutation expressed, can either raise or lower serum cholesterol levels due to its interaction with low-density lipoprotein receptors (Cohen *et al.*, 2006; Zerhouni, 2014). Wild-type PCSK9 interacts with the low-density lipoprotein receptor, this interaction leads to the targeting of the receptor, and any bound low-density lipoprotein cholesterol, for degradation. In some cases mutations in PCSK9 result in the formation of a protein that can no longer bind to the low-density lipoprotein receptor, thus the receptor is no longer degraded and can therefore return to the cell surface, further reducing serum cholesterol levels. Other mutations can result in a PCSK9 protein with increased protease activity, which leads to a depletion in low-density lipoprotein receptor levels and thus causes reduced low-density lipoprotein cholesterol uptake and therefore higher serum cholesterol levels (Zerhouni, 2014). These observations, coupled with the fact that a small percentage of the population have mutations which result in PCSK9 not being produced, and show no adverse effects from this, have led to the rapid development of PCSK9 inhibitors, which are currently undergoing phase 3 clinical trials (Sheridan, 2013).

Thus in the case of PCSK9 it would seem likely that a purely genomics driven approach would find it high

impossible to explain the complex mechanisms underlying what appears to be, a relatively simple system where one gene is directly responsible for a disease phenotype. Whilst genomics has been, and will continue to be, a major contributor to our understanding of the function of individual genes alone it has been less successful at elucidating the dynamic behavior of complex biological systems that are key to understanding disease (Peitsch, 2014). To this end, it would seem that the integration of genomic data with data from other sources, such as proteomics, metabolomics, and/or detailed phenotyping, along with the associated modeling tools, will hold the most potential to deliver modern treatment strategies and novel drug targets and drug candidates that take into account the complexity of disease physiology.

Proteomics and Metabolomics

Proteomics attempts to identify, and quantify the abundance of, proteins, the primary functional units of signaling networks and the principle target of drug discovery efforts. As such proteomics, utilizing the most notable proteomic technology, mass spectrometry, can provide important information as to the signaling network state of cell populations and has seen increasing usage in target identification and validation studies.

The recent development of more powerful mass spectrometers, combined with novel sample preparation and fractionation protocols has facilitated the use of global proteomics studies to identify novel drug targets (Veenstra, 2006; Sleno and Emili, 2008). In these studies global protein levels can be detected and compared between healthy and diseased samples, either from patients affected by a specific disorder or *in vitro* or *in vivo* models of disease. These studies typically result in the identification of hundreds of differences, thus an ongoing key challenge is the design of additional validation assays, or computational models, to explain these observations and prioritize the most notable drug targets (Veenstra, 2006).

An additional central aspect of global proteomics studies is the ability of mass spectrometers to detect posttranslational modifications. One such example of this is protein phosphorylation, which has been shown to be a key mechanism for regulating signaling network function. In addition, the recent clinical successes of drugs targeting protein kinases has led to increased drug discovery efforts focusing on the role of phosphorylation in disease states (McConnell and Wadzinski, 2009).

Finally, proteomics has also seen extensive use in mechanism of action studies, which can be used to elucidate the target of a molecule with a known biological effect (Sleno and Emili, 2008). In these assays the proteins bound to the molecule of interest can be isolated and identified using affinity chromatography, protein microarrays, or activity-based probes. In each case, protein lysates are mixed with the molecule of interest, the proteins or peptides binding to this molecule can then be identified via tags (e.g., fluorescent or radioactive markers) or purified and identified via mass spectrometry.

Metabolomics, which can also be performed using mass spectrometry (or nuclear magnetic resonance) measures the

level of endogenous chemicals and small molecules in a system and can thus provide important information regarding system dynamics, i.e., the processes occurring in the cell and those which have occurred. In many cases it has been shown that metabolic changes have a causative role in disease progression, thus by identifying these changes metabolomics can potentially identify new targets for therapeutic intervention (Rabinowitz *et al.*, 2011; Robertson and Frevert, 2013).

Data Integration

It is becoming apparent that biological systems cannot simply be understood by the analysis of one-type of data (Gomez-Cabrero *et al.*, 2014). As such, the integration of multiple types of omics data is now commonplace. This type of data integration is referred to as 'horizontal integration,' which attempts to explain systems-level changes from individual components (Lauffenburger, 2012). There are multiple methods for integrating these sources of data, but they generally focus on three tasks: identifying the network scaffold to describe the connections between components; deconstructing the network into its composite modules to infer the organization and active portions of the network; and the generation of systems models to simulate and predict network interactions driving phenotypic changes (Joyce and Palsson, 2006). To date studies utilizing data integration methods have predominantly focussed on transcript (mRNA expression) data and methods to integrate this with other data sources, such as proteomics or metabolomics (Berg, 2014; Zhang *et al.*, 2010). Whilst improvements in both omics technologies and data integration methods are still required results so far suggest that data integration will be pivotal for understanding how systems function and has already proven to have clinically relevant applications, most notably in multiple sclerosis and cancer (Joyce and Palsson, 2006).

Network Medicine

The omics technologies and the growth of modern systems biology has given rise to a new methodology for target selection and drug identification, termed 'network medicine' (Creixell *et al.*, 2012; Pawson and Linding, 2008). Pioneering work, discussed below, has demonstrated that cellular components are highly interlinked in complex inter- and intracellular signaling networks. As such diseases are most usually caused by abnormalities within these networks, rather than aberrations in single genes (Pawson and Linding, 2008). It can therefore be expected that drug therapies should target these networks and their dynamics in particular. Whilst it can easily be imagined that network properties and/or dynamics can be affected by a single drug, if designed with this in mind, there has also been considerable attention given to therapies involving multiple targets. The efficacy of this multi-target approach has been particularly successful developing therapies for AIDS, cancer, and depression (Barabasi *et al.*, 2011). Indeed moving forward it would seem likely that the most complex diseases will require more complex treatment strategies.

Properties of Networks

Biological systems are wired in complex interconnected networks, which when exposed to perturbation can, and often do, give rise to secondary effects and adaptations in the network itself (Janes and Lauffenburger, 2013). These biological networks are not arranged arbitrarily, but are instead governed by a set of organizing principles (Barabasi and Oltvai, 2004; Barabasi *et al.*, 2011). Firstly, biological networks cluster into what are termed 'modules.' These modules have a high number of internal connections but only have a relatively low number of external connections. Secondly, biological networks are comprised of nodes, for example, genes or proteins, which are linked together in a nonrandom manner. Within these networks there will be a large number of so-called 'hub' nodes. Hub nodes are highly interlinked nodes which serve one of two functions, either acting inside a module to regulate a specific cellular process (party hubs) or to link between modules and thus regulate between processes (date hubs). Thirdly, within a biological network there will only be a relatively short distance between nodes. This means that perturbing one node is very likely to have an effect on many other nodes within the vicinity and could potentially have an effect on the comprising module and even the network itself. This would of course be particularly likely if the perturbed node is also a hub. Finally, biological networks contain 'bottlenecks.' Bottlenecks are nodes through which the shortest path between pairs of nodes is often found and are thus frequently 'essential genes,' i.e., critical for the organisms survival. However, only about 25% of the known human genes have a demonstratable link to disease (Gillham, 2011). It is therefore possible to further characterize the network attributes that are specific to disease genes and thus predict their locations within networks (Goh *et al.*, 2007; Barabasi *et al.*, 2011). Firstly, of the known disease genes only ~20% are also essential genes, which are often hubs or bottlenecks and expressed in multiple tissues. In comparison, disease genes are usually tissue specific, do not encode hubs and are found most usually at the periphery of interaction networks. An interesting exception to that rule are the cancer-related proteins, which are more likely to act as hubs within protein interaction networks (Kar *et al.*, 2009). Secondly, nodes of a network driving disease tend to cluster. Thus if a few disease nodes are identified it is likely that other disease-related components will be found in their network vicinity in so-called 'disease modules.'

These observations have led to the theory of the diseaseome (Goh *et al.*, 2007), a biological network in which diseases are the nodes and the links between nodes are various molecular relationships arising from disease-associated cellular components, genes in the case of the human disease network described in Goh *et al.* (2007). In this way, multiple studies have shown that diseases can be linked based on their associated genes, their shared metabolic pathways and the microRNAs regulating the expression of disease genes (Barabasi *et al.*, 2011; Lee *et al.*, 2008; Lu *et al.*, 2008; Park *et al.*, 2009). Indeed it has also been shown that patients are at an increased likelihood of developing disease in the network vicinity of diseases they are already suffering from and that the number of links a disease has correlates with mortality rates (Barabasi *et al.*, 2011; Park *et al.*, 2009). An interesting example

of this is diabetes mellitus and Alzheimer's disease, which share a genetic link, as illustrated in the human disease network (Goh *et al.*, 2007). Whilst the pathology of Alzheimer's disease is still debated the brains of Alzheimer's sufferers have been shown to contain certain protein deposits, such as amyloid plaques and neurofibrillary tangles, which are also found in the brains of patients who died of diabetes. In addition, irregular expression of genes encoding insulin and its receptor has also been noted in patients with Alzheimer's disease. As such, there are now some clinicians that refer to Alzheimer's disease as type 3 diabetes and suggest that it can be treated with antidiabetes therapies (de la Monte and Wands, 2008).

Targeting Networks

There are now a number of studies which have targeted biological networks specifically in order to identify drug targets or novel therapies. One particularly compelling example of this has recently been published by the Yaffe laboratory at MIT. In this study it was shown that epidermal growth factor receptor (EGFR) inhibitors, if given at least 4 h prior, can increase the activity of doxorubicin by up to 500%. Importantly, a combination of an EGFR inhibitor and doxorubicin given at the same time showed no significant increase in activity compared to doxorubicin alone. In addition, the additive effect of EGFR inhibitor pretreatment on doxorubicin activity was only seen in triple negative breast cancer cells (compared to hormone sensitive and HER2 overexpressing cells). An investigation into the mechanism behind this novel observation showed that, in triple negative breast cancer cells EGFR inhibition resulted in a dynamic network rewiring, unmasking an apoptotic process involving the activation of caspase-8 (Lee *et al.*, 2012). Following this initial discovery a nanoparticle was developed to deliver this drug combination and has subsequently been used to test, and confirm, the effect in *in vivo* models (Morton *et al.*, 2014). Given that clinical trials are already planned there could be a very short turnaround time from the discovery of this novel therapy to it actually being utilized in patients.

These findings help to illustrate the fact that drugs, even if they are designed to have one target, will have network level effects, and that these can be taken advantage of, to create novel therapies (Erler and Linding, 2012; Hopkins, 2007). Even for individual drugs, particularly protein kinase inhibitors, it has been known for some time that their effect is most likely due to the fact that they act on multiple signaling kinases (Hopkins, 2007).

One potential caveat is that the novel network targets identified by systems biology approaches may not be drugable by conventional means. Thus, in combination with the identification of novel targets we will also require novel drugs.

New Methods for Drug Targeting

One rapidly emerging technology that could potentially solve this issue is small interfering RNA (siRNA) therapies. siRNAs are a type of synthetic RNAi molecule that are potent gene-specific inhibitors. In the case of siRNAs drug design is simple, there are already siRNAs readily available for all the known

genes in the genome. This can be extended further such that siRNAs can be designed to be transcript (Bolduc *et al.*, 2014) or even mutation specific, even if the mutated gene differs from the wild-type version by just a single base (Brummelkamp *et al.*, 2002). Thus, if advantageous to do so, siRNA therapies could be 'personalized' toward specific disease genes.

The major limitation of siRNAs however is the fact that they are degraded in the blood, and do not traverse the cell membrane. They therefore require potentially complex delivery mechanisms in order to be effective. Whilst progress in this regard is being made effective delivery mechanisms are not widely available, nor are they currently effective for all tissues (Wu *et al.*, 2014).

We therefore stand at an interesting juncture. We are learning more about disease networks and their effects on systems than ever before, but there is an intrinsic need for better identification of drug targets and drug candidates with which to treat them. However, meeting these challenges will undoubtedly lead to great improvements in the drug discovery process.

Index

Notes

Cross-reference terms in italics are general cross-references, or refer to subentry terms within the main entry (the main entry is not repeated to save space).

The index is arranged in set-out style with a maximum of two levels of subheading. Major discussion of a subject is indicated by bold page numbers. Page numbers suffixed by *T* and *F* refer to tables and figures, respectively; vs. indicates a comparison.

This index is in word-by-word order with hyphens within index headings are ignored in the alphabetization. For example, sweating is alphabetized after sweat test, not after structural matrices or C-family is after CetZs, and not at the start of the C section. Prefixes and terms in parentheses are excluded from the initial alphabetization.

Where index subentries and sub-subentries pertaining to a subject have the same page number, they have been listed to indicate the comprehensiveness of the text.
